Abstract

In the last two decades, the construction sector in UAE has been expanded to include a high range of tall and supertall buildings. Geographically, this region is surrounded by multiple earthquakes, such as the Zagros Fold and Thrust Belt. Additionally, the Makran Subduction Zone shows an activity source indicating a relatively high seismic risk. A similar situation motivated a research trend in China to simulate an earthquake on a city scale. The research objectives cover developing programming architecture to adapt to parallel computing concepts. Moreover, it targets creating simplified models that can indicate behavior key parameters with fewer DOFs. Both directions pushed into estimating the losses of the simulated hazard within moderate computers. However, the computational complexity of nonlinear simulations was not the only obstacle. The uncertainty in/among the problem modules; (ground motions intensity, structure simulations, damage analysis, and losses estimations) represents another significant concern. In 1995, the structural engineering community established performance-based engineering principles as a probabilistic design process instead of the traditional deterministic philosophy. Additionally, the Computational Modeling and Simulation Center (SimCenter) adopted this methodology into a software platform divided into microprograms. This architecture was designed to be generic to fit different problems according to the type of hazard, simulation, or data availability variation. In 2010, the Regional Resilience Determination (R2D) was released to provide a software package automating this methodology using a graphical user interface. A research plan is proposed to produce a step forward for realistic seismic simulation that includes the conclusion of previous studies and custom development for the UAE location. The objective is to produce an example of an end-to-end framework for seismic risk assessments that integrate with digital transformation trends such as Building Information Modelling (BIM) and the Geographic Information System (GIS). The scope of this investigation is a virtual dataset for RC tall buildings on a dense grid map that considers the variation in building location, material properties, building height, and seismic activity source.

Keywords: Seismic damage, High-fidelity structural model city-scale, Regional seismic, Parallel computing simulation, Tall buildings, Loss estimation, Nonlinear time history analysis.

Chapter 1: Introduction and Background

1.1 Introduction

In recent years, the real estate sector in UAE witnessed a significant development in the construction of tall buildings and iconic structures. Unfortunately, this area lacks data regarding seismic events and definitions of structural design considerations to be applied. Generally, the UAE is subjected to relatively high seismic risks, according to **Table 1** and **Figure 1**. Several studies indicate that, on average, three seismic events per year affect UAE based on observations from 2000-2006. For example, a moderate earthquake ($M_b=5$) shook a vast area in the North-East of UAE on March 11, 2002, and was accompanied by smaller foreshocks and aftershocks [1]. On November 27, 2005, and September 10, 2008, more complex earthquakes with magnitudes of $M_b=5.9$ and 6 started at the Qeshm Island region in the Hormozgan province of Southern Iran. Their impacts extended and were widely felt in Northern UAE, leading to the evacuation of some areas. In addition, two local earthquakes (with $M_b=3.7$ and 3.9) occurred in the Eastern region of UAE on March 10 and September 13, 2007, respectively. In 2018, a Seismic Hazard Analysis (SHA) study obtained many of UAE's geophysical parameters; PGA, soil type, geology, slope, and fault line distance [2].

Figure 1: A map of $M_b=4$ to $M_b=9$ earthquakes in the Arabian plate since 1970 [3].

Table 1: The primary seismic risk sources in the UAE [4], [5].

Seismic Risk Source	Description
The Zagros Fold and Thrust Belt	A series of major blind thrust faults capable of generating $M_b \sim 7$ earthquakes.
The Makran Subduction Zone	Shallow dipping seismic source $\sim 6^\circ$ that steepens to $\sim 19^\circ$ South of Iran's coastline. It produced an $M_s=8$ earthquake in 1945.
The Zendan-Minab Fault System	A complex faulting system was created by the Makran subduction zone joining the Zagros fold and thrust belt. It is capable of generating moderate/large earthquakes.
The Sabzevaran Jiroft Fault System	Has a similar seismogenic potential to the Zendan-Minab fault system, located further East.
Oman Mountains and the Dibba Line	A region is exhibiting features of faulting and a history of active tectonics. The 2002 Masafi earthquake originated in this region.
The West Coast Fault	Crosses the cities of Dubai and Abu Dhabi and passes very close to Ra's Al Khaymah. There is limited information about its activity (debatable existence).

This research aims to establish a robust, scalable, and intelligent framework for seismic risk assessment and damage estimation in some UAE regions/cities. Moreover, the framework will be compatible with trending civil engineering technologies: BIM and GIS. In addition, it will utilize the collected data in a machine-learning application. The concept of BIM was first introduced by a not-for-profit organization called **BuildingSMART**. It can simply be defined as a standard for proceeding with engineering projects, where there is a centralized data model instead of many files with different formats, and all project stages are reflected in it. This concept allows more collaboration among owners, designers, contractors, and stockholders. Moreover, it facilitates tracking of the project's progress, coordination, early clash detection, and facility management. Technically, **BuildingSMART** published Industry Foundation Classes (**IFC**) in an open international standard (ISO 16739-1:2018) format that can digitally describe the whole building assets. Additionally, it enables interoperability among different software. On the other hand, GIS is recognized as a framework for gathering, visualizing, and analyzing spatial data as an integration between geography science and data analysis. Many types of data are organized into multi-layers, then visualized into maps and 3D scenes. Analyzing data can better understand some patterns and allow for better decisions. GIS concepts were prolific for many engineering

problems, specifically infrastructure designs and urban planning. In smart/digital city simulations, the integrated GIS/BIM solutions retrieve and reuse vital data through each stage of the structure's life cycle. Thus, merging BIM and GIS data provides more efficient workflows and can be helpful on many scales, as explained in **Figure 2**. GIS data is necessary for planning operations regarding infrastructures, such as rail networks, airports, bridges, and roads. In post-construction, BIM models can provide specific data for GIS layers regarding building, facility management, and GIS visualization for 3D scenes. In this study, both BIM and GIS are used to provide data for seismic risk analysis as another application of GIS/BIM integration.

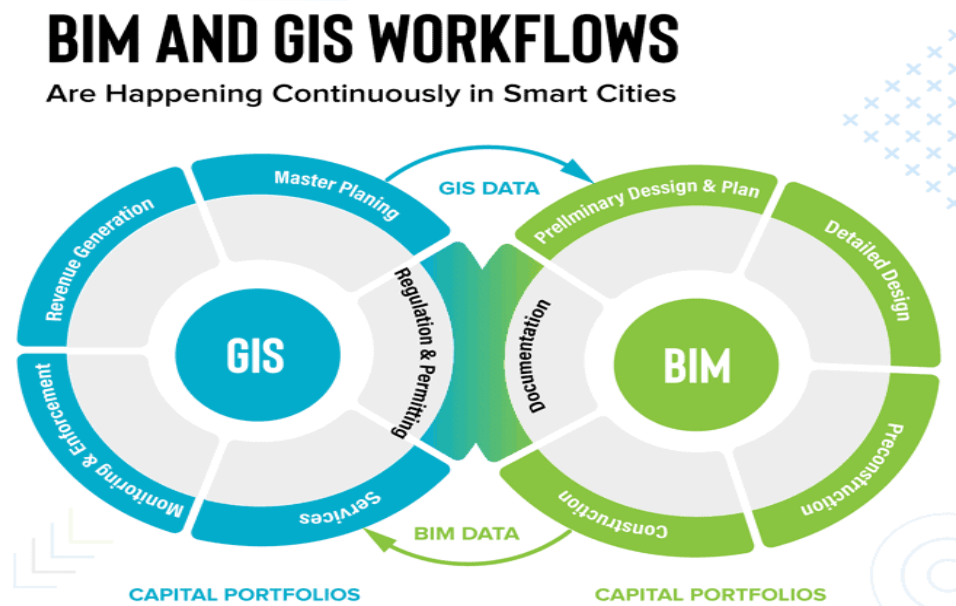

Figure 2: Benefits of GIS/BIM integration in smart cities [6].

1.2 Problem Statement

The UAE region represents a crucial case where a growing construction sector, including many mega and iconic buildings, is subjected to various distant and local earthquake sources, causing high seismicity levels. The main problem here is caused due to the wide diversity in estimating seismic levels, followed by an ambiguity among structure designers to agree on the design response spectrum. According to the Uniform Building Code (UBC'97), Dubai has been classified to be in zone zero (with no seismic requirements), with an estimated PGA, based on 475 years return period, of 0.15g. In 2013, the local authorities raised these requirements to zone 2B for buildings higher than nine stories and 2A for other buildings, based on Dubai Seismic Network (DSN).

Thus, some of the existing structures could be designed for underestimated seismic conditions.

Moreover, previous studies for this region mostly focused on comparing the performance of different structural systems using parametric studies of reference archetypes and earthquake records. However, a city-scale risk assessment study is urgently required to evaluate the effect of the previous variation regarding seismicity levels on the existing structures. But, in the meanwhile, regional seismic simulations have highly complex and computationally challenging problems. The aspects of complexity can be listed as follows:

- **Data Collection:** a dense amount of data is required to start this simulation. The required GIS data are for seismic resources and buildings' locations. Additionally, the attributes required for the adopted loss and damage analysis methodology. Usually, extensive work is required to build these databases from different resources and may be from different formats.
- **Computational cost:** The number of required nonlinear structural analyses equals the number of buildings multiplied by the number of seismic events. This number requires a huge computational capacity for storage and processing.
- **Uncertainties:** Conceptually, the structure performance can be assessed into four modules: hazard analysis, structure analysis, damage analysis, and loss analysis. According to this methodology, each module develops a certain margin of error, leading to accumulative expected error for outputted values.

1.3 Research Significance

The GIS-based risk assessment study for Dubai by [7] could be considered the first step in UAE regional simulations. Heavy work was included in the data collection aspect, where Dubai was divided into several neighborhoods, and the dominating usage classified each area. Also, the number of buildings in each neighborhood was estimated approximately according to the population density. However, a more profound methodology will be implemented in this research as another advanced step toward fully realistic city-scale simulation. Many significant changes are determined through all performance-based stages: hazard, structural, damage, and loss analyses. The research significance of the proposed study can be summarized as follows:

- An "Earthquake Scenario Simulation "will be performed for the hazard analysis stage instead of using reference records. This change would incorporate the effect of the location on the input ground motions for structural analysis. The region would be divided into 2D grids, and an input ground motion would be generated for each grid according to an earthquake prediction equation, as shown in **Figure 3**.
- A wider range of archetypes will be included in the structural analysis stage. Seventeen archetypes will be adopted with a high variation in building height from low-rise to high-rise (from single story to 50 stories) and other building properties, such as occupancy.
- Investigating calibrated models concept for the structural analysis to achieve simulations with personal computer capabilities. The MCS model will simulate low-rise and mid-rise archetypes, while the NFMS model will be utilized for high-rise buildings.
- Implementing PEER PBEE methodology and following HAZUS-MH 2.1 manual [8] to determine the collapse probability and DL parameters (like monetary loss and injuries) for included assets.

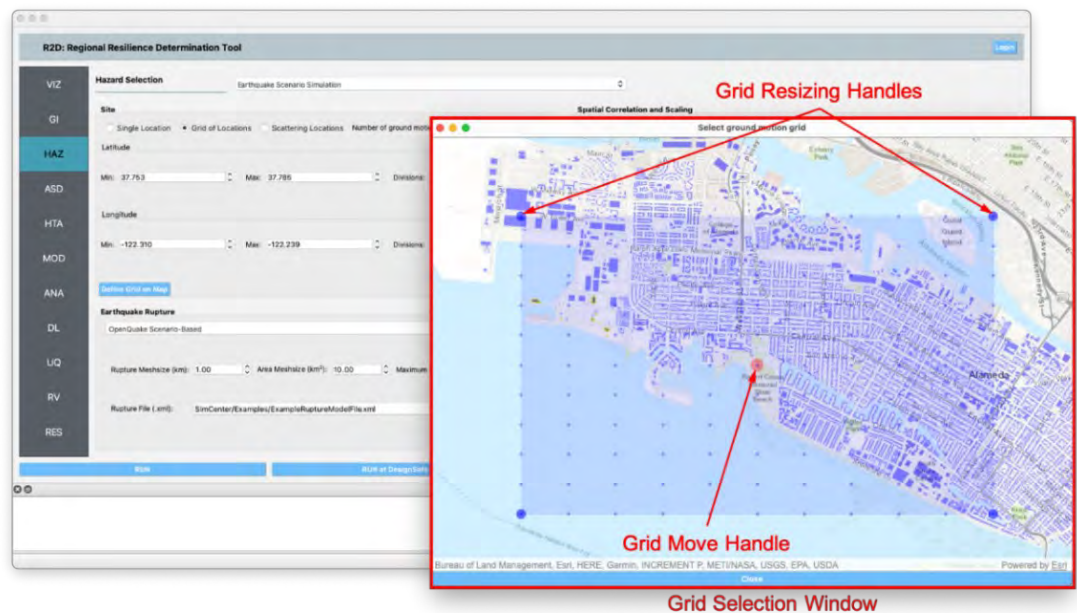

Figure 3: Earthquake scenario simulation based on a user-defined grid map.

1.4 Objectives

The main objectives of this research are:

1. Performing an "Earthquake Scenario simulation" to investigate the effect of asset location on the involved earthquake record based on ground motion prediction equations.
2. Development of an archetype building portfolio for Dubai, UAE, and associated special geographic distribution in a GIS-compatible format [GIS maps].
3. Perform a regional seismic simulation for the Dubai region that handles computational and uncertainties challenges.
4. Quantification of the expected losses in Dubai, UAE, under seismic hazard; Precisely, probability of collapse, economic losses for repair (or reconstruction), and expected injuries.
5. Identify critical building types, locations, structural types, and heights for various seismic hazard intensities.

1.5 Scope

The scope of the proposed research can be defined as follows:

1. The research is dedicated to estimating damage and losses due to seismic disasters only. Other risk resources not included like; wind, floods, .etc.
2. The study will be based in Dubai, so the collected GIS Buildings database is expected to reflect the demographic properties of this region. Also, the required "Earthquake Scenario Simulation" is limited to region location.
3. Seventeen reference buildings that vary according to height and occupancy were selected to reflect common structures in the region. Their properties are shown in **Tables 5** and **6**.
4. The R2D [9] software package will be utilized to perform a regional simulation. It utilizes Opensees [10] in nonlinear structure analyses, Dakota [11] for UQ modules, and HAZUS-MH 2.1 manual [8] for DL analyses and also contains an embedded package for "Earthquake Scenario Simulation."

1.6 Methodology

This research extensively reviews the literature about UAE seismicity, the effects of seismicity, performance-based earthquake engineering, and computing regional earthquake frameworks. The study's main aim is to perform a virtual example on a city scale using 17 reference models. The MCS model will be utilized for low-rise and medium-rise structures. The designed tall building models will be calibrated to an

equivalent NMFS model to facilitate several simulations within regular PC capabilities. The R2D [9] software package will be utilized to perform a GIS investigation. This package provides a GUI for an end-to-end regional earthquake framework that includes all stages of a PBED process. It will be used to perform an earthquake scenario simulation for each grid in the UAE region to select the most likely earthquake record. The primary outputs are the damage cost and probability of collapse for each asset in the virtual database. As shown in **Figure 4**, The workflow can be organized into three major phases;

- Earthquake scenario simulation: the studied region will be divided into grids, and an input ground motion will be assigned to each grid. Studied earthquake sources can be filtered according to the maximum distance and minimum and maximum magnitude. The ground motion record at each record is formulated from included resources based on a "Ground motion prediction equation" such as Abrahamson, Silva & Kamai (2014) [12].
- Assuming buildings database: many reference buildings should be selected according to the required variation. A high-fidelity FEM should be determined for nonlinear analyses. These archetypes will be distributed on the map to simulate neighbors' usage.
- Regional simulation: a nonlinear dynamic analysis will perform for each asset in the database by assigning the input ground motion in the closet earthquake grid. Then, damage and loss analysis will be performed to relate collapse probability, economic losses, and injuries to EDPs. All estimated data will be visualized in a GIS map to deduce relationships between building parameters and loss outputs.

Tables 2 and **3** demonstrate the parameters of adopted reference buildings, where the cost of archetypes was estimated according to [13]. They classified them into five Low-rise buildings, three Mid-rise buildings, and nine High-rise buildings. The detailed FE element model is required to deduct the MCS model for low-rise and medium-rise. Instead, a procedure was proposed by [14] to estimate the hysteresis parameters of each floor and implemented in R2D [9]. Three different elastic design response spectrums were selected to simulate ambiguity in defining seismicity level. These spectrums were defined by [15], and their key parameters are ($S_s = 0.18$ g, 0.42 g, and 1.65 g) and ($S_1 = 0.06$ g, 0.17 g, and 0.65g) for low, medium, and high seismicity levels. The chosen

models show a variation in structure systems, usage, and design seismic level according to the common types in the UAE region. On the other hand, a detailed FE is required to calibrate the NMFS model for high-rise buildings [16]. Nine tall buildings are assumed as commercial construction, with RC shear walls, for years from 2000 to 2010.

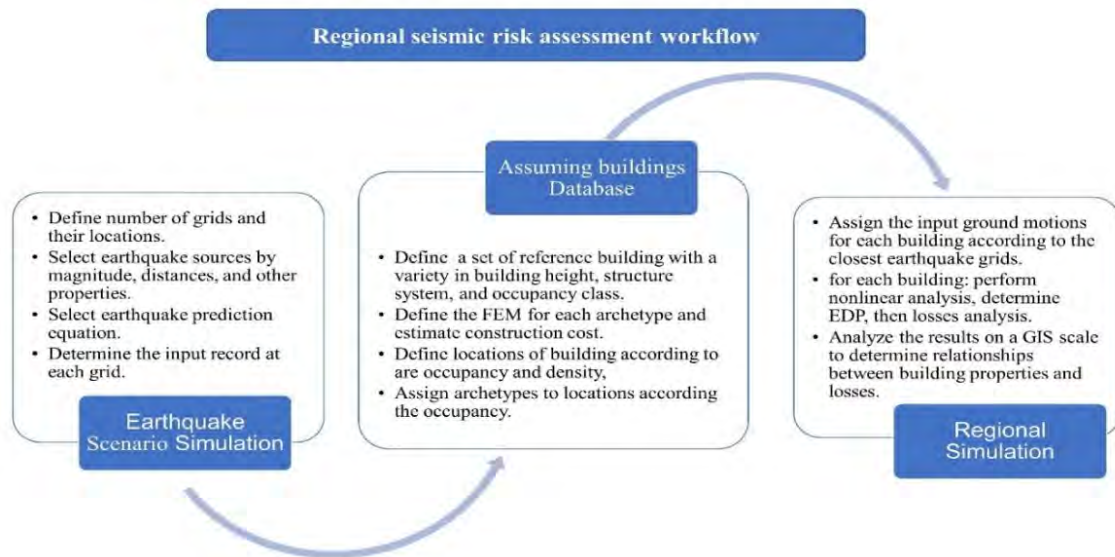

Figure 4: Flowchart for regional earthquake workflow.

Table 2: Parameters of low-rise and medium-rise archetypes.

Label	Number		Occupancy Class	Structure Type	Plan Area (Ft ²)	Cost (AED K)	Seismic Level
	of Stories	Year built					
LR_RES_F1	1	1981	RES1	RM1L	1615	675	Low
LR_RES_F2	2	1995	RES3	C1L	2690	2025	Low
LR_RES_F3	3	2000	RES3	C2L	4300	4850	Low

MR_COM_F7	7	2010	COM1	C2L	5382	18805	Middle
LR_IND_F1	1	2003	IND2	S1L	10764	4500	Middle

NOTE: RES refers to Residential Occupancy; RES1 is for a single-family and RES3 is for multiple families. COM refers to Commercial Occupancy; COM1 and COM2 are for Retail Trade and Wholesale Trade. IND2 means light industrial factory. RM1L, C1L, C2L, and S1L are representing Reinforced Masonry Bearing Walls, Concrete Moment Frames, Concrete Shear Walls, and Steel Moment Frames for structure types.

Table 3: Parameters of high-rise archetypes.

Label	Number of Stories	Cost (AED)	Year built	Material properties		Plan	
				Fc' (MPa)	Fy (MPa)	Area (Ft ²)	Seismic Level
HR_COM_F10	10	58485					
HR_COM_F15	15	87727	2000	50	420		
HR_COM_F20	20	115970					
HR_COM_F25	25	146211					
HR_COM_F30	30	175454	2005	60	420	9685	High
HR_COM_F35	35	204696					
HR_COM_F40	40	233939					
HR_COM_F45	45	263181	2010	70	500		
HR_COM_F50	50	292423					

NOTE: The occupancy class is COM4 and the structure type is C2L for all high rise archetypes. COM refers to Commercial Occupancy; COM4 is for Professional/Technical Services. C2L are representing structures with Concrete Shear Walls.

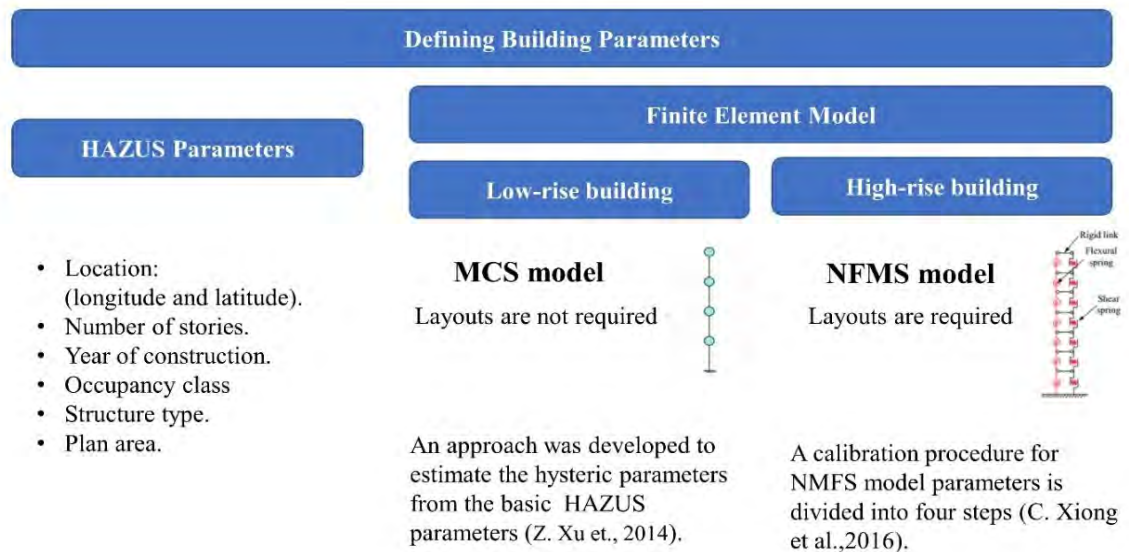

Figure 5: Flowchart for the required data to define a building.

The reference buildings will be distributed in Dubai neighbors according to the usage and population density, and these data are available and published by [7]. The selected earthquake records for each grid will be selected according to the scenario simulation component in R2D [9]. A series of regional simulations will be executed for a differently designed model. The outputs can be represented in the form of GIS maps

for collapse probability and economic loss. According to the parameters of total height and shear wall strength, these maps will be a heuristic reference for designers. This research will represent a first-step stage of regional simulations in UAE, where the distant goal is to collect and digitalize an actual building inventory database.

1.7 Thesis Organization

The thesis is organized into six chapters, described as followings:

- **Chapter 1: Introduction.** Presents a general introduction of the research background, importance, main objectives, scope, and methodology.
- **Chapter 2: Literature Review.** Provides an extensive review of accomplished research studies for performing regional simulations and overcoming computational obstacles. Additionally, it includes a brief description of performance-based earthquake engineering and the uncertainty in Dubai Seismicity.
- **Chapter 3: Design of Tall Buildings Archetypes.** It provides the applied loads' definitions and the resulting designed section for all structural elements.
- **Chapter 4: Calibrating NMFS Models for Tall Buildings Archetypes.** Describes the process of calibrating NMFS models from the designed archetypes. Also, it provides the properties of calibrated models and the accuracy in their pushover results relative to the FE models.
- **Chapter 5: GIS Databases for Building, Ground Motions, and Risk Assessment Results.** Presents the properties of included building and ground motions databases, the assumptions used to generate these data, and the final generated results and maps.
- **Chapter 6: Conclusions and Recommendations.** It contains a summary of regional results and the effects of building properties on the damage and loss estimation outputs.

Chapter 2: Literature Review

2.1 Challenges and Research Aspects

Since the beginning of 2010, there have been approximately 120 super high-rise buildings higher than 300 m, based on a statistic inventory by CTBUH. This survey included either completed or under-construction tall buildings and obtained that they are mainly located in regions with rapid economic development, namely: China, UAE, and the USA (there are 47 in China, 28 in the UAE, and 18 in the USA). However, most developing cities are threatened by severe seismic disasters. This risk created a critical and motivational need to develop a scientific prediction of seismic damage platform, providing early warning of potential seismic risks. The main challenges were; (1) achieving precise flexural-shear deformations for each building with efficient computational techniques that could consume limited time, practical computational demand, and storage resources, and (2) implementing a performance-based engineering framework that includes all uncertainties and probabilistic inputs and present stakeholders' outputs like injuries and economic losses. The following paragraphs contain the progress achieved by several studies on related objectives, such as implementing a more brilliant programming architecture to minimize computational costs; developing simplified numerical models to accurately reflect the inter-story earthquake damage with fewer DOFs.

2.2 GPU-Based High-Performance Computing

Generally, computers have two main processing units, the CPU and the GPU. The essential, fast, and versatile processing component is the CPU. It is composed of a few cores with lots of cache memory that can handle some software threads at a time. In contrast, the GPU was originally designed for high-performance computer graphics visualization, costing much less than a traditional CPU platform. Although the performance of a single GPU core is relatively weak compared to a CPU core, the total parallel and float computing capabilities of the GPU are much higher. The GPU contains hundreds of cores that break complex problems into thousands or millions of separate tasks and work them out at once. Thus, the concept of GPGPU was subsequently proposed to perform high-performance computing tasks in addition to visualization. In 2006, NVIDIA Corporation released CUDA, a GPGPU platform. It depends on utilizing the CPU for serial processing and GPU for parallel processing.

This innovation significantly reduced programming difficulties and enhanced its computational performance. As shown in **Figure 6**, the CUDA processing flow is: (1) Copy data from main memory to GPU memory, (2) CPU initializes the GPU compute kernel, (3) GPU's CUDA cores execute the kernel in parallel, and (4) Retrieve results from GPU memory back into main memory. The computing capacity of each GPU core is relatively weak, and the data exchange between different GPU cores is very time-consuming. This makes the flow only suitable for some tasks having specific characteristics: (1) the computing task can be divided into many relatively short subtasks, (2) each subtask has a moderate computing workload and can be individually implemented on a single GPU core, and (3) different subtasks do not require data exchange throughout their life-cycle.

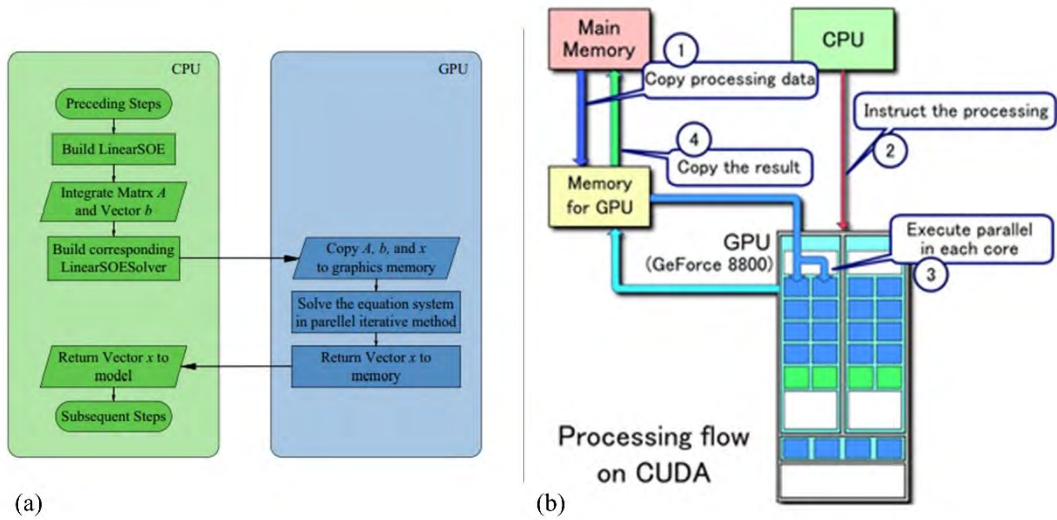

Figure 6: Typical processing flow on CUDA [17].

Although OpenSees [10] is a well-known computational tool that has been widely used in earthquake engineering research, it is not computationally efficient in cases of tall and supertall buildings [10]. For large structures with hundreds of DOFs, a nonlinear time-history analysis is very time-consuming (may take several weeks to complete), and most of this time is consumed by SOE solving. For this scale of structures with beam and shell elements, the stiffness matrix, mass matrix, and damping matrix (if the classical Rayleigh damping is adopted) usually exhibit significant sparse characteristics. Although, the existing framework of OpenSees implements three sparse SOEs: SuperLU SOE, UmfPack SOE, and SparseSYM SOE. Direct methods, such as triangular and elimination decomposition, are integrated into these solvers. However, these methods are not suitable for GPU-based parallel computing. In 2016, a GPU-

based SOE solver, named CuSP solver, was developed to be compatible with the existing software architecture [17]. This development was based on: (1) Using iterative algorithms, such as the conjugate gradient (CG) algorithm, Bi-CG algorithm, and generalized minimal residual (GMRES) algorithm. These algorithms can be implemented in a parallel processing logic; (2) Building a solver class that inherits from the LinearSOESolver class of OpenSees. The kernel algorithm of the solver is packaged in a DLL form to achieve compatibility. The corresponding scripts of CuSP are provided as obtained herein [18]. A case study was conducted to compare the performance of a CPU-based solver to a GPU-based solver with almost the same price for Hardware platforms. Two benchmark models were selected. The first was the Building 2N model, a 141.8 m height model based on a frame-core tube building. It contained 23,945 nodes, 23,024 fiber-beam elements, and 16,032 multi-layer shell elements. The second model was 632 m in height, called the Shanghai Tower model. It contained 53,006 nodes, 48,774 fiber-beam elements, and 39,315 multi-layer shell elements. The study included performing THA, adopted from the El-Centro EW ground motion, with 1000 cm/s² and 400 cm/s² PGA values for the Building 2N and Shanghai Tower models, respectively. Results of the speed-up ratios indicated that using the two GPU-based solvers is up to 9–15 times faster than using the CPU-based solver.

Logically, seismic damage simulation for a dataset of buildings can be a suitable task for a GPGPU processing workflow if each building is a subtask and is simulated with macro models (e.g., concentrated-mass story model). In this case, the application will meet the previously mentioned characteristics as the computing workload of each subtask is sufficiently small for a single GPU core. Additionally, there should be little interaction between different buildings during an earthquake. A program architecture was developed for this problem [19]. Its main concept was utilizing the parallel computing capacity of GPU for the nonlinear time-history computing of individual buildings. Moreover, the CPU was used for data reading, computational tasks, and copying data between the two memories inside the CPU and GPU. Also, the communication between the CPU and GPU was reduced to prevent communication delays. The efficiency of this procedure was measured and compared to the default CPU processing flow with a similar price platform. The inputted test case was 100 six-story buildings with the same parameters. The bilinear hysteretic model was selected for the inter-story hysteretic model, and the nonlinear contained 8000 steps. In conclusion, when a single building is computed, the CPU computing time is 7% of the GPU

computing time. Such a result is expected because of the difference in performance between a single CPU core and a single GPU core. However, as the number of buildings increases, the CPU computing time increases significantly, corresponding with a less increase in GPU computing time due to parallelization. As a result, when 1000 buildings are computed, the GPU computing time can be 1/40 of the CPU computing time.

2.3 High-Fidelity Computational Models for Earthquake Disaster Simulation of Tall Buildings

The collapse simulation of complex buildings can be achieved based on the FE method using the proper element models, constitutive material laws, and elemental-failure criteria. For example, a study for collapse simulation of the Shanghai Tower subjected to extremely strong earthquakes was conducted by [20]. Shanghai Tower, located in Lujiazui, Shanghai, is a multi-functional office building containing 124 stories and is ranked as the second tallest building globally. The total height of the central tower is 632 m, while its structural height is 580 m. The structural design implemented a hybrid lateral-force-resisting system named "mega-column/core-tube/outrigger."

Figure 7: (a) The whole FE model of Shanghai Tower [20]; (b) Sketch of the lateral-force-resisting system of Shanghai Tower.

The multi-layer shell element prototype, shown in **Figure 8** (a), was adopted to model the core-tube RC walls, which is based on the principles of mechanics of composite materials. It is made up of layers with different thicknesses and material properties, allowing it to simulate coupled in-plane/out-of-plane bending. This is typically accompanied by in-plane direct shear and coupled bending-shear behavior of RC shear walls. The internal forces of the shell element can then be calculated, following the constitutive material laws, by integrating the stresses of different concrete and steel layers, as explained in **Figure 8** (b). This model accurately represents nonlinear behavior in RC shear walls through well-defined constitutive laws of concrete and steel. In OpenSees, a new high-performance flat shell element NLDKGQ is developed [21]. It consists of a planar membrane element GQ12 and a plate-bending element DKQ. The GQ12 element has two translational (along x- and y-axes) and one rotational (around the z-axis) DOFs per node, while the DKQ element has one translational (along the z-axis) and two rotational (around x- and y-axes) DOFs per node. The combination of these two elements results in 6 DOFs per node in an NLDKGQ element, as explained in **Figure 8** (c). Consequently, the NLDKGQ elements can be readily connected to the beam elements without resorting to the extra embedded beam elements, significantly reducing the modeling workload.

Figure 8: NLDKGQ element developed by [21]: (a) A 4-node shell element with multi-layer section; (b) Stress variations in concrete and steel layers in the multi-layer shell element; (c) Degree of freedoms of the NLDKGQ element in the local coordinate system.

The external frame and outriggers are simulated using a fiber-beam element model, which is capable of simulating the axial-flexural coupling behavior of RC

frames. Each fiber has its uniaxial constitutive law, and all the fibers in the same section follow the "plane section" assumption. Each cross-section segment (i.e., the flange and web) is divided into nine fibers to ensure computational accuracy. Conversely, this model cannot be accurate for mega-columns because their dimensions are so large that they go far beyond the general conception of columns. As shown in **Figure 9** (a), the designed section for mega-columns is nearly 20 m² with a steel ratio of 6.22% and a reinforcement ratio of 1.16%, which significantly confines the mechanical behavior of the concrete. The concrete, shaped steel, and rebar were modeled for a detailed FE model using hexahedral solid elements, quadrilateral shell elements, and truss elements. Despite the high fidelity of the detailed FE model, its computational workload is very time-consuming for implementing solid elements. Another approach, a simplified model with much fewer DOFs, is adopting multi-layer shell elements combined with truss elements. The concrete, the rebar distributed along the Y-direction, and the web of the shaped steel were modeled using multi-layer shell elements. However, the shaped-steel flange and the rebar distributed along the X-direction were modeled using truss elements. The accuracy of the simplified model approach was validated through various numerical simulations study of the mega-columns under pure compression, pure bending, bending with compression in one direction, biaxial direction, *etc.* Subsequently, this study proposed using the simplified model of the mega-columns in the global structural seismic response analysis.

Figure 9: Typical cross-section of mega-column with detailed and simplified FE models: (a) Typical cross-section of mega-column (unit: mm); (b) Detailed FE model of mega-column; (c) Simplified FE model of the mega-column.

2.4 Simplified Models for Earthquake Disaster Simulation of Multiple Scales Buildings

The high-fidelity FE model integrates the fiber-beam elements for beams/columns and multi-layer shell elements for shear walls/core tubes. Furthermore, it enables an accurate simulation of the entire collapse process of tall and supertall buildings with sufficient adaptability. It requires a considerable workload and computational recourses, causing practical constraints in its usability. To address this issue, simplified models have great potential to facilitate academic research and practical applications. Such models can represent buildings' critical nonlinear and dynamic characteristics whilst being computationally effective. Selecting the simplified model is unequivocally based on the lateral drift mode of the original model. Usually, the shear deformation is common for moderate multistory buildings, while tall buildings are subjected to flexural-shear deformation mode.

In the case of shear mode lateral drift, the MCS model is a multi-degree-of-freedom model that can accurately calculate the local damage to different stories. Lu-Qu's model is used as a hysteretic model to represent inter-story behavior [19]. The calibration process (explained in **Figure 10**) is mainly about setting hysteric model parameters to achieve a matching nonlinear cyclic pushover with the typical FE model. As a practical procedure within an urban area, buildings can be divided into different classes according to their structural types and building properties. Then, one MCS model can be identified for each class. Furthermore, a 6-story RC frame building was a benchmark for investigating the accuracy of the MCS model. THA was performed using the widely known El Centro record with a 600 cm/s^2 PGA for refined FE and calibrated MCS models. Results showed an excellent agreement respecting the displacements of each story subjected to base shear or time history (**Figure 11**). The method explained in **Figure 11** requires an undefined number of trials to adjust the hysteric parameters, which could be highly time-consuming for an urban area study of thousands of buildings. Thus, an approach was developed to estimate the hysteric parameters from the basic building information (i.e., number of stories, height, year built, structural type, floor area, and occupancy) and the HAZUS database. It provided good accuracy and high computational efficiency in several studies such as; [14], [22].

Figure 10: (a) The multistory concentrated-mass shear model for a building; (b) The inter-story hysteretic model [19]

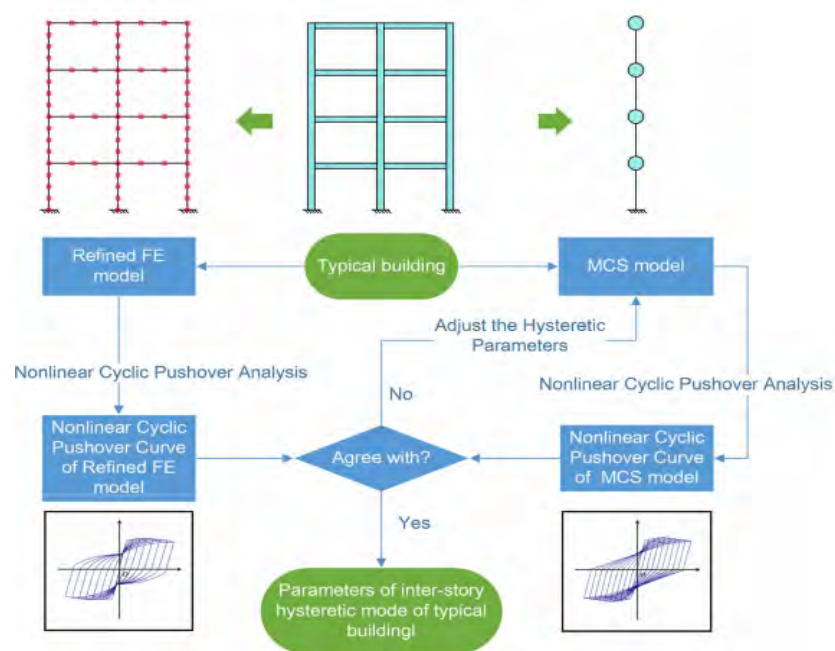

Figure 11: Method for determining the parameters of the hysteretic model in selected typical buildings [22].

Most super tall buildings depend on hybrid systems for lateral loads, resisting mega column-core, tube-outrigger systems, and mega-braced frame-core tube systems. The deformation modes of these structural systems are typically a combination of flexural deformation and shear deformation. The flexural-shear coupling elastic continuum model ("flexural-shear model" for short hereafter) was proposed to predict the seismic responses and dynamic characteristics with fewer computational resources [23]. As shown in **Figure 14**, the model consists of a flexural and a shear cantilever beam representing respectively flexural and shear components of structural

deformations. A finite number of axially rigid links are added, connecting both beams to ensure lateral deformation compatibility at the same story height. Also, partial differential equations were used to describe the dynamic response of this model under a ground motion acceleration.

Figure 12: Validation of MCS model in comparison to refined FE model [22]: (a) Refined FE model of the 6-story RC frame building; (b) Top displacement versus time histories predicted by the FE and MCS models; (c) Lateral hysteretic behavior of the FE and MCS models in the bottom story.

The Shanghai Tower model is used to validate the accuracy of the flexural-shear model in predicting the elastic seismic responses. The cross-sections of the core tube and the mega columns reduce almost linearly from the bottom to the top. Linear varying mass distribution is assumed in the simplified model. Performing modal analysis on both models confirmed the reliability of the flexural-shear model in reporting the basic dynamic properties. **Figure 13** compares both models regarding the first vibration periods in the x-direction, where the error of the simplified model can be neglected.

The nonlinear MDOF flexural-shear (NMFS) model was proposed by [16] to simulate the nonlinear behavior and damage on different building stories. Instead of continuum flexural and shear beams in the flexural-shear model proposed by [23], each story was discretized into nonlinear shear and flexural springs explained in **Figure 14** (a). The NMFS model was originally developed to simplify RC frame-shear wall structures and standard hybrid lateral resistance systems and was widely used for

designing tall buildings. The shear spring represents the shear deformation mode resulting from RC frame behavior. Similarly, the flexural spring represents the flexural deformation mode resulting from shear walls. Following the elastic continuum model, rigid links are used at each story level for lateral deformation compatibility. They recommended adopting bi-linear and tri-linear backbone curves (Figure 14 (b)) for flexural and shear springs.

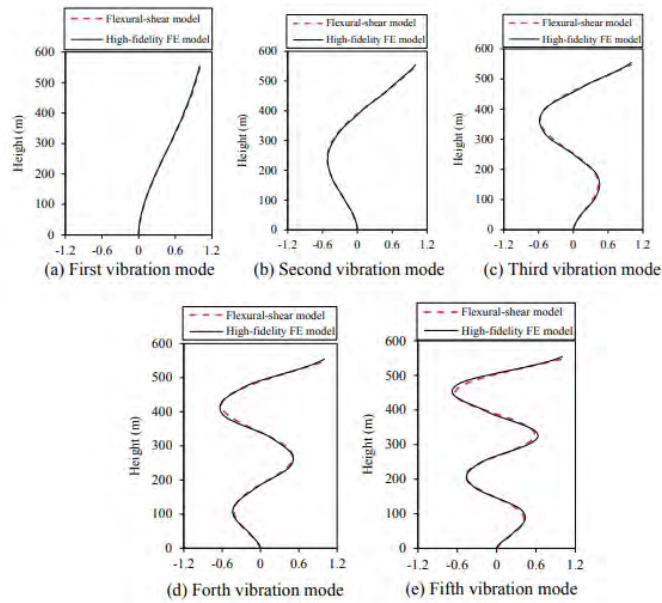

Figure 13: The first five vibration modes of the Shanghai Tower [23].

Figure 14: (a) Comparison of the elastic continuum [23] and nonlinear flexural-shear models [16]; (b) Bi-linear and tri-linear backbone curves of HAZUS

The proposed calibration procedure for NMFS model parameters is illustrated in **Figure 15**, and it is divided into four steps: Calibration of the elastic parameters, calibration of the yield point, calibration of the peak point, and calibration of the hysteretic parameter.

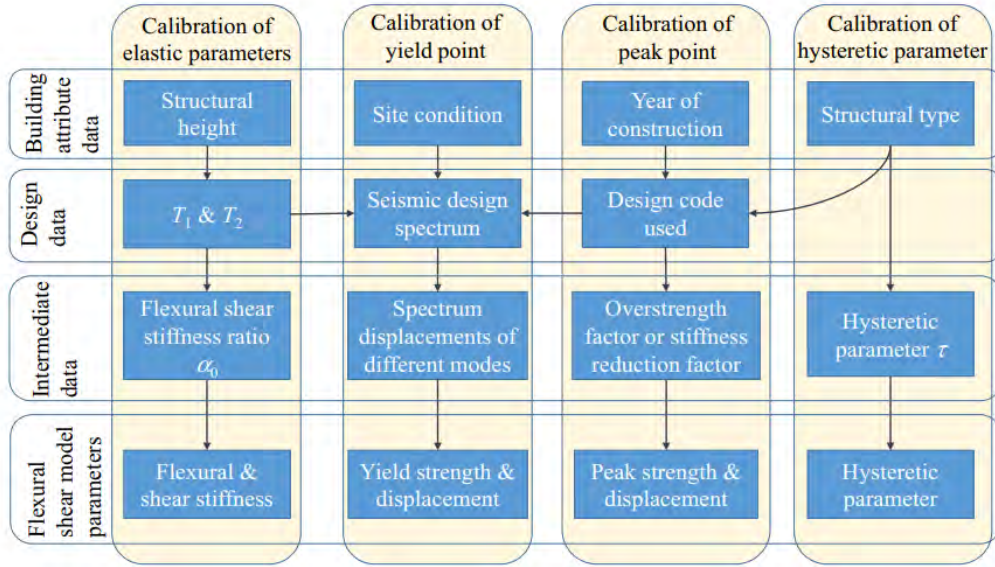

Figure 15: Calibration Process for NMFS model [15].

Two tall buildings are included to validate the calibration process. Three NMFS models are established and calibrated for both buildings. Then, their seismic responses are compared with those of the refined FE models. Buildings A and B are a 15-story RC frame-shear wall structure and a 42-story RC frame core-tube structure. The refined FE models of the two buildings (shown in **Figure 16**) are established using the general-purpose FE software MSC.MARC. The nonlinear analysis included 22 earthquake records (recommended by FEMA-P695). Bi-linear curves calibrate the NMFS-Bi model, and the NMFS-Tri- η model behavior is assumed with Trilinear curves, while the stiffness reduction method ($\eta = 0.7$) is used for peak point calibrations. In addition, the ductility factor method ($\mu = 4$) is adopted for the NMFS-Tri- μ model. The results of all these models compared to the detailed FE model are represented in **Figure 17**.

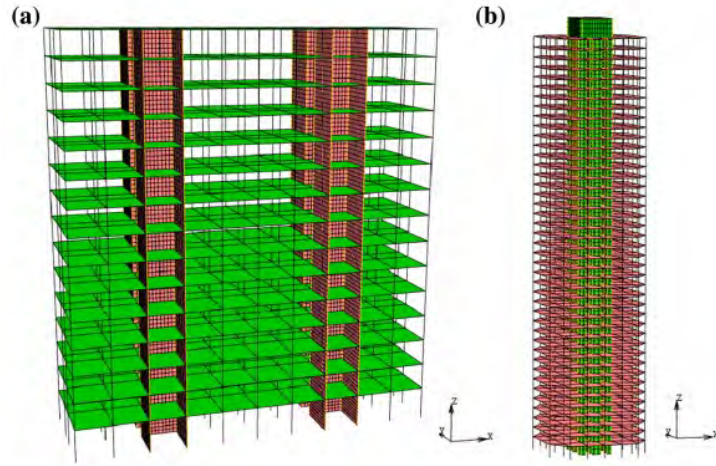

Figure 16: Benchmark models for simplified NMFS model calibration by [15]: (a) Building A (a 15-story RC frame-shear wall); (b) Building B (a 42-story RC frame core-tube structure).

2.5 Performance-Based Earthquake Engineering (PBEE)

After the consequences of the 1994 Northridge and 1995 Kobe earthquakes, structural designers started to adopt performance-based engineering concepts instead of the traditional deterministic specifications. The traditional philosophy is bounded by two primary variables: earthquake intensity and corresponding damage for structural and non-structural elements. The acceptance criteria are preventing low-intensity damage, only repairable damage in medium-intensity, and preventing a collapse in high-intensity earthquakes.

In 1995, The Structural Engineers Association of California (SEAOC) published its PBEE Vision 2000 report, which is considered the most remarkable document for the first-generation PBEE in the USA. It defines a framework for performance-based earthquake design (PBED) by selecting the desired system performance at various earthquake intensity levels, as shown in **Figure 18**. Seismic hazard intensity can be described as frequent, occasional, rare, or very rare events. Moreover, the system performance levels are classified as fully operational, operational, life safety, and near collapse. The design objective is determined based on the private property owners, e.g., residential or commercial buildings, or by the public resiliency requirements, e.g., hospital buildings. Additionally, other subsequent documents of first-generation PBEE, e.g., FEMA-356 [24], introduced a similar framework with different descriptions for hazard levels and system performance. Despite the conceptual progress, this framework has several shortcomings related to the system performance estimation; (1) The structure analysis procedure determines the engineering parameters, but the uncertainties in the numerical model are not considered. (2) The element performance is defined by a deterministic relationship with the engineering measures. These relationships can be calibrated from experimental tests or analytical models without a probability distribution. (3) The overall system performance is assumed to be equal to the worst performance of any component.

Figure 18: SEAOC Vision 2000 [25] recommended seismic performance objectives for buildings.

The Pacific Earthquake Engineering Research Center (PEER) developed a more robust methodology fitting the complex, multi-disciplinary nature of the problem and

overcoming the deficits of earlier PBEE methods. Unlike first-generation PBEE frameworks, estimating the system performance includes variables that reflect the direct interests of various stakeholders, such as monetary loss, repair duration, and casualties. System performance assessment is based on a rigorous probabilistic framework consisting of four logical, sequential components: hazard analysis, structural analysis, damage analysis, and loss analysis, as shown in **Figure 19**. Many publications have summarized and explained PEER methodology, such as [26]–[28].

The hazard analysis considers earthquake sources and facility characteristics to evaluate ground motion Intensity Measures (IM). It requires selecting nearby faults and collecting their descriptions, i.e., source-site distance, magnitude-recurrence frequencies, and fault mechanism. The facility data is defined in two terms: the location (O) and design characteristics (D), i.e., the fundamental period of vibration and foundation type. Engineering seismology relationships, such as ground motion prediction equations, are employed to quantify desired variables from these inputs, including issued uncertainties. The Intensity Measures variables might be Peak ground acceleration (PGA), peak ground velocity (PGV), spectral acceleration at the period of the first mode (Sa(T1)), spectral shape, and ground motion durations. The next generation will include a higher range of data variety, less dispersion, and more confidence in expecting shaking intensity. The hazard curve shows hazard analysis results by plotting the selected Intensity Measures versus their mean annual frequency (MAF) of exceedance [29]. These results can be transformed to IM versus POE (Probability of Exceedance) in "t" years by using Equation ((1) for the Poisson model, as shown in **Figure 19**.

$$p(IM) = 1 - e^{-\lambda(IM)t} \quad ((1))$$

Where $\lambda(IM)$ is the annual frequency of exceedance of IM, and t can be considered as the duration of the facility life cycle.

After quantifying IM variables, the next step is to perform structural analysis to indicate structure responses for these ground motions. This process involves developing a computational model, performing nonlinear simulations, and calculating EDPs. This step's uncertainty is from the numerical model parameters such as mass, stiffness, strength, .etc. Generally, EDPs characterize the response in terms of deformations, accelerations, induced forces, or other appropriate quantities. Also, EDPs can be

determined for local structural components or overall building behavior. For a structural component, element forces (i.e., axial and shear forces) and plastic deformations (i.e., rotations and deflections) are examples of practical EDPs. The global building behavior can be described in EDPs such as inter-story drift, floor velocity, floor acceleration, roof drift, .etc. Global EDPs can indicate damages for different damageable components (both structural and non-structural elements). For example, inter-story drifts measure structural system damage [30], while floor acceleration is used for non-structural equipment, e.g., office or laboratory buildings [31]. PEER developed the incremental dynamic analysis (IDA) procedure to investigate the relationship between ground motions intensity and structural simulations. This procedure is based on repeating structural simulations with scaling input ground motions. The resulting series of values can establish statistical relations between IM and EDP or the POE of EDP at a certain given IM. The results of structural analysis can be summarized as the determination of probability distribution functions (PDFs) of EDP (e.g., EDP_j) for a given IM (e.g., IM), as shown in **Figure 19**. The number of PDFs equals α multiplied by β , where α is the number of IM data points and β is the number of considered EDPs.

Damage Measures (DM) are the quantitative variables describing the physical damage to structural and non-structural elements and contents. These measures can be related to given EDPs through the damage analysis conditional probability relationships. Conditional relationships can be calibrated by experiment results or previous earthquake reconnaissance reports. PEER continuously develops conditional probability relationships for different components by collecting previous test data or performing other experiments. This procedure requires defining damageable groups, as each group includes facility parts that are similarly affected by certain EDP. For example, Bohl [32] proposed a methodology for damage analysis of a steel moment frame building. It considered 16 damageable groups; the structural system, exterior enclosure, drift-sensitive and acceleration-sensitive non-structural elements, and office content on each floor. Multiple DMs levels describing the type of required repair for a damageable group should be defined. For example, the three DMs levels of structural elements defined by [33] are light, moderate, and severe (or collapse). They respectively represent repair with epoxy injections, repair with jacketing, and element replacement. A single EDP value cannot be mapped deterministically into a certain DM level because this value can occur in different structural response scenarios and with

different behaviors. Instead, any DMs level can occur according to this value but with different probabilities. Fragility curves are established to show the variations in POE of all defined DMs in different EDP values, as shown in **Figure 19**.

Figure 19: Analysis stages of PEER PBEE methodology [34].

The last step of the PEER PBEE methodology is the loss analysis to estimate Decision Variables (DVs). These variables reflect the direct interests of various stakeholders in the design. Some of the DVs are economic loss, repair duration, and the number of fatalities and injuries. A loss function is determined to calculate the POE of the losses for different damageable groups at different DMs. The total number of loss functions required for a facility is γ multiplied by λ , where γ and λ are the number of DMs and damageable groups, respectively. The accumulative loss curve can be calculated based on the total probability theorem. The probability of the n^{th} value of the DV is according to Equation ((2) in the form of a triple summation.

$$\begin{aligned}
& p(DV^n) \\
& = \sum_m \sum_i \sum_k p(DV^n | DM_k) p(DM_k | EDP_j^i) p(EDP_j^i | IM_m) p(IM_m)
\end{aligned} \tag{2}$$

The structural engineering community started to realize the impact of the PBEE methodology. It was included in several benchmark studies such as [30], [31], [35].

2.6 Open-Source Packages for Regional Earthquake Simulations

The Computational Modeling and Simulation Center (SimCenter)[36] develops many software tools specialized for natural hazard engineering (NHE) problems. The main goal is to provide an application framework for researchers to use, build, and extend scientific workflows for natural hazard simulations. This framework implements integrated relationships among three units; model, scientific workflow, and application. The model is a conceptual component with a particular role or analysis procedure. Practically, each model can be simulated by many software applications. However, a workflow is a collection of models integrated into a sequence to automate multi-step solutions. This approach requires developing pre- and post-processors for existing applications for data parsing. The end-user can customize the workflow by selecting the in-use application for each model depending on the nature of the problem, available input format, and the required specifications. Finally, the SimCenter application is defined by a workflow as a backend package connected with a wrapping frontend User Interface (UI). The purpose of UI components is to define workflow applications and their parameters, generate input file(s), and present output results. The architecture of the SimCenter application framework, shown in **Figure 20**, has an intelligent design because it considers the following principles: the architecture is designed as a modular framework to integrate with external applications or datasets. This feature can save the repeating work of an existing application and guarantee futural scalability and interoperability. For example, the SimCenter team developed pre-and post-processors to benefit from existing applications such as OpenSees [10], OpenFOAM [37], and PEER Strong Ground Motion Databases [38]. Moreover, they developed additional applications and linked them with the framework, such as Building Recognition using AI at Large-Scale (BRAIL) [39], to automate collecting building inventory data.

A scientific workflow was proposed to provide an open-source platform and a standard architecture for solving regional hazard simulations and loss estimation problems [14]. Conceptually, the workflow is divided into a sequence of modules, where each is determined to provide resulting data based on defined inputs. This design allows for future developments or enhancements in modules. It could also smoothly replace proposed applications with others, under the condition of preserving the format of inputs/outputs used in other models. The source code is published into the GitHub hosting platform. Some applications, programmed in C++ or Python, are provided for each module, while the data exchange through workflow modules is saved in JSON format.

Figure 20: The architecture of the SimCenter application framework [36].

The definition of inputs, outputs, primary function, and available applications for each module, as well as the assumptions considered, are briefly plotted in **Figure 21** and explained as follows:

- (1) Create Building Information Model (BIM): This module aims to create JSON files for each model that contains properties required in other modules. The definition of the BIM model requires the building's integer ID, name, floor area (in square feet), height (in feet), number of stories, location, replacement cost, replacement time, occupancy (residential, retail, office, .etc.), and structural type (W1, S1, C1, .etc.).

- (2) Create Event: This module contains applications that can provide a separate input event file, such as ground motions records, concerning the location of the building. SHA-GM is a seismic hazard analysis application that depends on user-defined ground motion prediction equations and ground motion records databases. It provides ground motions over a grid of sites, in which each building is then assigned to ground motions at the nearest grid selected by the nearest neighbor algorithm.
- (3) Create Structural Analysis Model (SAM): This module is meant to provide a structural model to perform THA analysis. MDOF_LU is a program developed to achieve this function. It maps buildings' properties to MCS models assuming the mass per unit area equals 1000 kg/m^2 . The Tri-linear backbone curve is adopted to simulate inter-story behavior. The critical parameters of Trilinear curves are selected based on HAZUS technical manual recommendations (Table 5.7 and Table 5.5) for certain structural types and the number of stories.
- (4) Create Engineering Demand Parameters (EDPs): EDPs include the maximum inter-story drifts, the floors' absolute accelerations, and residual displacements. These parameters can be determined by corresponding to node IDs defined in the SAM file.
- (5) Perform Simulations: This means reading a SAM file, creating an OpenSees model, performing THA analysis, and setting the required EDP. For the previously mentioned procedure of the MCS model and earthquake events, the OpenSeesSimulation program can be used for processing this module.
- (6) Create Damage Loss (DL): The primary function is determining the damage states (defined by HAZUS: slight, moderate, extensive, and complete) and the cost of replacement/repair of each building. FEMA_P58_LU is a damage and loss assessment tool that Prof. Xinzhen Lu's research group developed at Tsinghua University based on the FEMA-P58 methodology. As explained in **Figure 22**, this procedure assumes a conditional probability where the damage state corresponds to the determined EDP using fragility curves. Then, the repair cost is defined by a look-up table. This procedure is described in Chapters 3 and 7 of [40].

Figure 21: Scientific workflow for regional earthquake simulations [14].

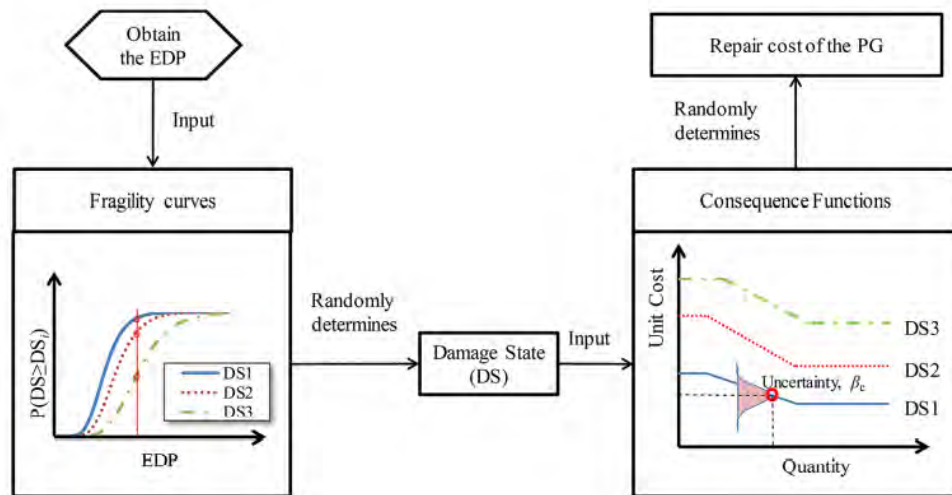

Figure 22: Estimating repair cost for a building component using the FEMA-P58 methodology [14].

On January 13, 2021, the SimCenter team released the first version of the Regional Resilience Determination R2D tool [9], which is a graphical user interface for the SimCenter application framework. It facilitates the process of defining studied events, building databases, and visual representations of maps and resulting DL ratios through integration with ESRI-ArcGIS SDK libraries, shown in **Figure 23**. The application was designed with an architecture of two components: frontend UI and backend applications. The front end was developed using the cross-platform QT framework to generate user inputs in the local machine. However, the backend is an application workflow written in C++ or Python that processes the critical analysis on a remote server (HPC utilizing resources available through DesignSafe). This design utilizes cloud computing concepts, particularly for large sets of data that require specific

computational resources and cannot fit with available PC potentials. The user manual, downloading source configurations, and solved examples are available on their website [9], [36].

Figure 23: UI and results visualization of R2D tool [9].

2.7 Examples of Applying Analysis to Urban Regions or Cities

A regional earthquake analysis was applied by to a medium-sized city in China called Shantou. The El Centro 1940 earthquake ground motion was implemented as a reference to perform THA on 7,449 buildings, and the MCS model was adopted for FE analysis. The results are represented in **Figure 24**, where the damage states are categorized into five sections (i.e., none, slight, moderate, extensive, and complete) as indicated in HAZUS [8]. Computationally, this required only 10 minutes in the processing environment of an i5 processor, 2.8 GHz, and 4-GB memory, which indicates the practical efficiency of the MCS model.

Figure 24: Regional earthquake analysis of Shantou city by [22]; (a) Buildings damage simulation (b) Seismic damage to buildings of a selected local area.

SimCenter workflow for regional seismic loss estimation [14] was applied on 1.8 million buildings (81% are single-story residential units and 17.3% are 2-story units) in the San Francisco Bay Area. The MCS was adopted for numerical modeling and for performing simulations for the M 7.0 Hayward Fault earthquake scenario. The map in **Figure 25** represents the distribution of estimated loss ratios for all buildings separated into five ranges. Results showed that 7.5% of the buildings are predicted to have a loss ratio greater than 60%. Single-story wood structures built before 1973 represent 62.6% of this sector. Based on this study, the computational efficiency can be considered acceptable since it consumed about three days using three moderate computers (with Inter(R) Xeon(R) CPU E5-2630 v3 @2.40 GHz).

Figure 25: Buildings loss ratios distribution in the Bay Area of San Francisco [14].

Nine tall buildings and two medium-rise RC frame buildings (details in **Table 4** and **Figure 26**) were selected to perform a regional simulation using the proposed NMFS model [41]. Also, El-Centro EW ground motion with PGA = 400 gals is adopted as a reference event for performing THA. Using a desktop computer with resources of 2.67-GHz Intel Xeon X5650 CPU and 48 GB of 1333-MHz DDR3 and RAM, the analysis process took only 261 CPU seconds to prove the importance of the NMFS model.

Figure 26: Regional earthquake study [16] : (a) 2D-GIS plan of buildings; (b) inter-story drift ratios at $t = 10$ s.

Table 4: Inventory of buildings included in the regional study [16].

Label	Name of building	Number of stories	Height (m)	Site condition	Year of construction	Structural type

These are just a few examples of the latest research in regional earthquake risk assessment. The field is constantly evolving, and new methods and tools are being developed all the time. As a result, it is important to stay up-to-date on the latest research to make informed decisions about earthquake risk mitigation. here are some of the latest journal papers on regional earthquake risk assessment in the last three years:

- In 2023, Sianko et al. [42] presented a framework for probabilistic seismic risk assessment (PRSA) for the city of Adapazari, Turkey. The framework is based on a Monte Carlo simulation approach, and it incorporates seismic hazard, vulnerability, and exposure models. The framework is used to assess the risk of earthquake damage for different return periods. The study also found that the risk of earthquake damage is not evenly distributed across the city. The most vulnerable areas are those that are located near active faults and those that have older, less seismically resistant buildings. The results of this study can be used to inform decision-making about earthquake risk mitigation in Adapazari. The study suggests that there is a need to focus on reducing the risk of earthquake damage in the most vulnerable areas of the city.
- In 2022, M.J. Smith et al. [43] published research describing a comprehensive earthquake hazard and risk assessment study program for the Canterbury region of New Zealand. The study includes the identification and characterization of earthquake sources, probabilistic hazard assessment, and formulation of earthquake scenarios.
- In 2022, a multidimensional urban earthquake impact simulation (MDUES) platform was developed by C. Hsu et al. [44] to simulate the dynamic seismic response of buildings and the damage they may incur due to earthquakes in urban areas. The platform was used to simulate an earthquake scenario in Taipei City, Taiwan. The results of the simulation showed that the earthquake-induced dynamic seismic response of buildings varied depending on their location and structural characteristics. The risk of building damage was also calculated, and the results showed that some buildings were more vulnerable to damage than others.
- In 2021, R. Adhikari et al. [45] presents a seismic risk assessment for Nepal that integrates seismic hazards with social vulnerability. The study uses OpenQuake

to compute the risk analysis and then integrates the results with socio-economic parameters.

- In 2019, G. Deiana et al. [46] reviewed the state of the art in regional earthquake risk assessment in Italy. The paper discusses the different approaches to risk assessment and the challenges that need to be addressed.

2.8 UAE Seismicity Uncertainties

The previous UAE seismic hazard investigations studies reported a high variation from no seismic hazard to very high seismicity, as shown in **Table 5**. For examples:

- In 1999, the Global Seismic Hazard Map Project (GSHAP) provided the PGA values for Europe, Africa, and the Middle East that consider 475-year return periods. The estimated Dubai and Abu Dhabi values were 0.32g and 0.24g [47], respectively, reflecting a very high-risk probability. No local seismicity activities were included in this research.
- In 2004, Abdalla and Al Homoud [48] disagreed with the GSHAP outcomes and considered it very conservative through a robust scientific investigation. Their research was based on Zagros thrust attenuation equations and assuming a bedrock. The estimated PGA values for Dubai are 0.14g, adopting 475 years as a return period and 10 % POE.
- In 2006, Sigbjornsson and Elnashai [49] provided a focused study on Dubai and the west coast fault as the primary source of seismic activities. It included the significant impact of dual earthquake situations from both distant and local sources. They estimated PGA values for Dubai were 0.16g and 0.22g corresponding to 10% and 2% POE, respectively.
- In 2008, Abdalla et al. [50] studied the effect of the earthquake that occurred on Qeshm island, Iran, in 2005 on Dubai's tall buildings. The recorded earthquake had a 6.2 body wave magnitude, 10 km focal depth, and 185 km epicentral distance to Dubai. They recommended increasing the seismic hazard level for high-rise buildings according to the distant resources' risks, especially the Makran subduction zone and Zagros thrust fault. Also, they suggested installing earthquake monitoring devices on important skyscrapers.
- In 2006, Dubai Seismic Network (DSN) [51] was established to record earthquakes from local and distant resources through four stations. From 2006

to 2014, a large number of regional seismic activities were recorded from faults surrounding the UAE, as shown in **Figure 27** (a). Additionally, local seismic activities are noticed from three main sources; (1) Masafi-Bani Hamid, (2) Northern Huwaylat, and (3) Wadi-Nazwa, as shown in **Figure 27** (b).

Table 5: Comparison of results for Dubai seismic hazard studies [52].

Study	PGA (return period = 475 years) (g)
Al-Haddad et al. [53]	< 0.05
Grunthel et al. [47]	0.32
Abdalla and Al Homoud [48]	0.14
Sigbjornsson and Elnashai [49]	0.16
Peiris et al. [54]	0.06
Musson et al. [55]	0.05
Aldama-Bustos et al. [56]	< 0.05
Shama [57]	0.17

The uncertainties in estimating the seismicity level in UAE regions caused ambiguity for designers regarding defining analytical loads and the best practices of the static systems and material properties. Several studies have been conducted in this area, like:

- In 2011, the seismic design factors had been investigated by [58]; (the Response Modification Factor (R), Deflection Amplification Factor (C_d), and the System Over-strength Factor (Ω_0)) for three reference buildings designed in Dubai of four, sixteen, and thirty-two stories. The chosen structure system was RC special moment resisting frames, and two different sets of ground motions were applied corresponding to 475 and 2475 return periods. The conclusion was that the seismic design level significantly impacts the building R factor, and they recommended period-dependent R and C_d Tables.
- Also, in 2011, a similar study was conducted by [59] for five shear wall buildings from 20 to 60 stories. Incremental Dynamic Analysis (IDA) results showed that R and C_d 's code values were very conservative. Also, higher values for Ω_0 were recommended.
- In 2012, the effect of the structural system on lateral behavior was studied by [60] depending on analyzing and designing four 20 stories buildings with

different systems. The chosen systems were Special Moment Resisting Frames (SMRF) and a dual system of SMRF with Special Shear Walls adopted for both RC and Steel buildings. It concluded that stiffer systems would be subjected to higher forces and accelerations while softer systems are expected to suffer higher drift and inelastic damage.

- In 2020, an investigation was produced by [61] that referenced twelve archetypes of buildings that include a variation in building height (6, 9, and 12 stories), design seismicity level (low, intermediate, and high), and type of shear wall (ordinary or special). They recommended being conservative in designing seismic intensity and utilizing the special RC shear walls for optimizing lateral behavior based on the probability of collapse and economic loss results.
- In 2022, three companion studies [62]–[64] compared the lateral performance of RC tall buildings with two layers of ductile coupled shear walls according to building heights (20, 40, and 60 stories), shear wall alignments, and concrete properties among normal concrete strengths and different Ultra-High-Performance Concrete (UHPC) materials. The results showed a significant impact for UHPC on structure performance and total cost aspects.

According to a large collected dataset from satellite images and site visits, a GIS-based risk assessment study for Dubai was conducted by [65]. They divided Dubai into 221 areas, and each area is classified by occupancy as residential, commercial, or industrial, as shown in **Figure 28** on a GIS map. The distribution of total buildings is weighted as 49%, 38%, 12%, and 1% for residential, commercial, industrial, and unidentified usage, respectively. Five reference archetypes were chosen for simulating all assets, with a variety in building height and structural system. The adopted seismic parameters were; $S_s = 0.71g$, $S_1 = 0.59g$, and $T_L = 8s$. The authors used a set of 44 strong earthquake records recommended by FEMA-P695 [66] in the performed nonlinear analyses. An Incremental Dynamic Analysis (IDA) of 25 increments was conducted to determine the collapse probability at three performance levels (by ASCE 41-17, [67]) Immediate Occupancy (IO), Life Safety (LS), and Collapse Prevention (CP). The results obtain that at the design and MCE levels, the probabilities of exceeding the CP limit state are low for all buildings, particularly below 10% for Buildings C1 and C4 and

slightly less than 20% for Building C5. Building C5 exhibited the least favorable performance regarding exceedance probabilities and maximum drifts.

Figure 28: The distribution of building occupancy GIS Map [7], [65].

Table 6: Details of the representative buildings utilized by the GIS risk assessment study [7], [65].

Building/HAZUS designation	LFRS	Number of stories	Material properties		Sector usage
			Fc' (MPa)	Fy (MPa)	
C1: low-rise RC frame	Ordinary moment-resisting frame	2	35	420	Residential
C2: low-rise RC shear wall	Ordinary RC shear wall	2	35	420	Residential
C3: midrise RC shear wall	Ordinary RC shear wall	6	40	420	Commercial
C4: high-rise RC shear wall	Special RC shear wall	12	40	420	Commercial
C5: high-rise RC frame	Special MRF	16	40	420	Commercial

Chapter 3: Design of Tall Buildings Archetypes

3.1 Description of Archetypes

The material properties and the number of floors of the selected high-rise buildings are shown in **Table 3**, while the unified floor layout and structural system are presented in **Figure 29**. The assumed layout is a double symmetric plan view for an office building that consists of five 20-foot-bays (6.0 m) in both North-South and East-West directions. The lateral resisting system consists of two shear wall layers (single shear walls in the edge perimeter and double shear walls connected with coupling beams in interior axes). For slabs, the f_c' is assumed to 4.0 ksi (28 MPa). Additionally, the associated loads are defined as per ASCE7-16 [24]; 42.5 psf (2.036 kPa) for Super Imposed Load (SDL), 7.5 psf (0.359 kPa) for the curtain wall (cladding) on the perimeter of each floor, 50 psf (2.394 kPa) for typical floors live load, 20 psf (0.958 kPa) for roof live loads, and the self-weight of the concrete slabs. The soil classification for the site will be taken as "D" as the code recommends when there is no specific soil exploration information available.

ASCE7-16 [24] specifies the response modification coefficient (R) and the deflection amplification factor (C_d) for specially reinforced shear walls as 6, and 5, respectively. While the applied elastic design response spectrum considered a high seismicity condition with ($S_s = 1.65 g$) and ($S_l = 0.65g$). A software package was developed to automate analysis and design processes for all reference models, where its source code is available through a GitHub repository [68]. It contains pre/post mediators for Opensees [10] to perform modal analysis and a nonlinear pushover. Additionally, this package contains functionalities to define vertical and horizontal loads as specified in ASCE7-16 [24]. The cross-section design checks are following ACI318-11 for structural concrete requirements [69] including the minimum reinforcement specifications for both column and shear walls. The designed sections were grouped in every 5 stories to simplify the layout. In Opensees, the columns and shear walls were represented by `dispBeamColumn` object [70] to reflect the reinforcement precisely using a fiber section [70]. The following two subsections outline the detailed design process and results of the gravity system and lateral force-resisting system of the nine buildings.

Figure 29: Typical floor plan view for tall buildings archetypes

3.2 Gravity System Design

The gravity system is designed to resist all vertical loads in addition to the deformation compatibility requirements. The columns are designed for bending moments and shear forces that are expected from earthquake excitation deformations to ensure structural stability. According to the IBC'12 [69], the maximum allowable inter-story drift is 2%. Equation (3) define how to calculate column stiffness (K) corresponding to the modulus of elasticity, the moment of inertia (I), and the floor height (L) assuming a rigid diaphragm behavior. Then the applied Bending-Moment (M) and shear force (V) can be estimated as functions of the deformed displacement (d). The vertical reinforcement ratio (ρ) should be from 0.01 to 0.08 according to ACI318-11 [69].

$$K = 12 EI/L^3 \quad (3)$$

$$V = K \times d \quad (4)$$

$$M = L \times V / 2 \quad (5)$$

All designed column sections with reinforcement details are listed in **Table 17** (Appendix A), while **Table 7** presents the reinforcement of the slab section.

Table 7: Typical Floors Slab Reinforcement Schedule.

Thickness	Top Reinforcement	Bottom Reinforcement	Remarks
20 cm	Φ 10 @ 14.00 cm	Φ 10 @ 14.00 cm	Additional Φ 10 @ 17.00 cm 2.5 m long provided over columns in both directions

3.3 Lateral Force Resisting System Design

According to ASCE-16 [24], the minimum number of modes required to determine lateral forces should guarantee modal mass participation of at least 90% of the actual mass in each orthogonal horizontal direction of response considered in the model. Opensees [10] was utilized to perform the modal analysis through the Eigen command [70], where the mass was lumped at one mode in the center of each story. As an alternative to performing an analysis to determine the fundamental period, The approximate fundamental period T_a can be estimated according to equation (6) ($C_t = 0.03$, $x = 0.9$, and H refers to the total Height). The computed fundamental period should not exceed (CuT_a) . For every mode shape (j), the participating horizontal force for the i^{th} floor can be estimated according to the equation (7)

$$T_a = C_t H^x \quad (6)$$

$$F_{ij} = \gamma_j \phi_{ij} S a_j W_i \quad (7)$$

where γ is the mode participation factor, ϕ is the modal deformation, $S a$ is the elastic response and W is the floor weight. This force should be multiplied by (R/C_d) . Then, the combination of mode shapes forces should be estimated using the square root of the sum of the squares (SRSS). The design lateral for the diaphragm at level x (F_{px}) can be determined as defined in the equation (8), ASCE-16 [24].

Table 8: Modal Analysis results

Ref.Building	Approximate Period		Computed mode shapes by Opensees [6]	
	T_a	CuT_a	T_1	
M1_10F_50RC	0.83	1.16	1.11	$T_a < T_1 < CuT_a$
M2_15F_50RC	1.20	1.67	1.94	$T_1 > CuT_a$
M3_20F_50RC	1.55	2.17	2.57	$T_1 > CuT_a$
M4_25F_60RC	1.89	2.65	3.49	$T_1 > CuT_a$
M5_30F_60RC	2.23	3.12	3.75	$T_1 > CuT_a$
M6_35F_60RC	2.56	3.59	4.53	$T_1 > CuT_a$
M7_40F_70RC	2.89	4.05	3.87	$T_1 > CuT_a$
M8_45F_70RC	3.21	4.50	5.65	$T_1 > CuT_a$
M9_50F_70RC	3.53	4.95	6.66	$T_1 > CuT_a$

$$F_{px} = \frac{\sum_{i=x}^n F_i}{\sum_{i=x}^n W_i} W_{px} \quad (8)$$

where the w_{px} is the tributary weight at level x. However, (F_{px}) should be not less than ($0.2 S_{DS} I_e w_{px}$) or more than ($0.4 S_{DS} I_e w_{px}$). ACI318-11 [69] determines two conditions for the cases of special boundary in reinforcement, refer to equations (9), and (10).

$$h_w/l_w < 2 \quad (9)$$

$$\frac{1.5 \delta_u}{h_w} \geq \frac{l_w}{600 c} \quad (10)$$

where the (c) refers to the compression zone in the shear wall section, and the drift ratio (δ_u/h_w) should not be less than 0.005. The length of special boundary reinforcements should not be less than the greater of ($C - 0.1 l_w$) and ($C/2$). According to these specifications, multiple trials were conducted for modal analysis and shear section checks until reaching a safe design for each model. The shear wall length (in-plan view) is kept constant throughout the building height. To avoid excessive out-of-plane slenderness complications in walls, the cross-sectional aspect ratio (l_w/t_w) is kept in the range (~6-12).

Figure 30: The details of special boundary reinforcement in the shear wall.

3.4 Cost Estimation for Structural Elements' Materials

The bill of quantities, reported in **Table 9**, shows the accumulative of concrete and steel materials required for designed superstructures. Slabs are the most demanding elements, they required from 72.44% to 52.26% of concrete volumes and from 72.61% to of steel weights. Slabs Quantities ratios are decreasing respecting to increasing the number of floors, unlike columns and walls. Columns require from 6.76 % to 12.01 % of concrete quantities and from 6.76 % to 12.01 % of steel quantities. While, Shear walls consume a range of 20.80 % to 35.73 % and 37.77 % to 52.02 % for concrete and steel, respectively. The estimated concrete and steel quantities per floor are 230.8 m³ and 22.28 tons for the “M1_10F_50RC” model. They gradually increase respecting the number of floors 319.924 m³ and 54.26 tons for the “M9_50F_70RC” model.

Table 9: Bill of Quantities of structural elements.

Ref. Building	Concrete Volume (m3)				Steel Quantity (ton)			
	Columns	Slabs	Walls	Total	Columns	Slabs	Walls	Total
M1_10F_50RC	156 (6.76%)	1672 (72.44%)	480 (20.80%)	2308	23.24 (10.43%)	161.76 (72.61%)	37.77 (16.95%)	222.77
M2_15F_50RC	214.8 (6.24%)	2508 (72.85%)	720 (20.91%)	3442.8	35.84 (10.69%)	242.64 (72.40%)	56.66 (16.91%)	335.14
M3_20F_50RC	273.6 (6.04%)	3344 (73.78%)	914.5 (20.18%)	4532.1	65.42 (10.88%)	324.27 (53.95%)	211.34 (35.16%)	601.03
M4_25F_60RC	332.4 (5.86%)	4180 (73.73%)	1157 (20.41%)	5669.4	94.81 (12.36%)	405.34 (52.83%)	267.11 (34.81%)	767.26
M5_30F_60RC	411.6 (5.87%)	5016 (71.57%)	1581 (22.56%)	7008.6	117.87 (11.98%)	487.55 (49.55%)	378.55 (38.47%)	983.97
M6_35F_60RC	1367.4 (13.80%)	5852 (59.07%)	2688 (27.13%)	9907.4	295.3 (20.01%)	570.13 (38.63%)	610.57 (41.37%)	1476
M7_40F_70RC	1456.8 (12.40%)	6688 (56.94%)	3601 (30.66%)	11745.8	307.83 (17.11%)	651.58 (36.22%)	839.51 (46.67%)	1798.92
M8_45F_70RC	1546.2 (11.64%)	7524 (56.65%)	4212 (31.71%)	13282.2	347.62 (15.63%)	736.44 (33.11%)	1140.14 (51.26%)	2224.2
M9_50F_70RC	1921.2 (12.01%)	8360 (52.26%)	5715 (35.73%)	15996.2	479.7 (17.68%)	822.05 (30.30%)	1411.23 (52.02%)	2712.98

According to these quantities, and assuming the cost of a cubic meter of concrete and a ton of reinforcement steel was assumed 235 and 2,200 AED, the cost estimations, in **Table 10**, are found. The total material cost of the designed archetypes are varying from 1.00 to 7.99 million. In other words, The cost of materials per floor is from 0.1 for ten floors archetype to 0.19 respecting 50 floors archetype million AED. Finally, the cost of the square meter for structural elements (without counting the wasted quantity) is in a range from 120 to 235 AED.

Table 10: Structural cost estimation.

Ref. Building	Structural Material Cost (million AED)			Avg. Per Floor	Avg. Cost per m2 (AED)
	Concrete	Steel	Total		
M1_10F_50RC	0.51	0.49	1.00	0.10	119.36
M2_15F_50RC	0.76	0.74	1.49	0.10	119.2

Chapter 4: Calibrating NMFS Models for Tall Buildings Archetypes

4.1 Introduction and Background

Instead of depending on multiple trials to adjust the hysteric parameters for the MCS models, a simplified and more effective calibration process has been developed to estimate these parameters from the basic building information and the HAZUS database [19]. The process can be explained as follows; the initial stiffness (K) and mass (M) are assumed to be uniform along with the height for regular structures. They are given according to equations (11) and (12), respectively.

$$[K] = k_0 \begin{bmatrix} 2 & -1 & 0 & \dots & 0 \\ -1 & 2 & -1 & \ddots & \vdots \\ 0 & -1 & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & 2 & -1 \\ 0 & \dots & 0 & -1 & 2 \end{bmatrix} \quad (11)$$

$$[M] = m [I] \quad (12)$$

Eq.(13) demonstrates estimating the first vibration period of the building (T_1) from the number of stories in the building (N)

$$T_1 = \frac{N}{N_0} \cdot T_0 \quad (13)$$

N_0 and T_0 are the numbers of stories and fundamental periods, respectively, of the typical buildings presented in Tables 5.5 and 5.7 of the HAZUS dataset [8]. The below equations from (14) to (15) explain in detail how to determine the backbone curve, shown in **Figure 10**, for an inter-story (i), according to HAZUS dataset [8] values for the yield capacity point (SD_y, SA_y), the ultimate capacity point (SD_u, SA_u), and the mode factor (α_1).

$$\lambda = \left(\frac{[\phi_1]^T [I] [\phi_1]}{[\phi_1]^T [A] [\phi_1]} \right) \quad (14)$$

$$k_0 = \lambda \frac{4\pi^2 m}{T_1^2} \quad (15)$$

$$V_{y,i} = SA_y \cdot \alpha_1 \cdot m \cdot g \cdot \Gamma_i \quad (16)$$

$$\eta_i = \frac{SA_u - SA_y}{SD_u - SD_y} \cdot \frac{SD_y}{SA_y} \quad (17)$$

$$\beta_i = \frac{SA_u}{SA_y} \quad (18)$$

$$\Delta_{c,i} = \delta_{co} \cdot h \quad (19)$$

where g is the acceleration of gravity and δ_{co} is the inter-story drift ratio at the threshold of the complete damage state. As shown in Eq. (20), Γ_i refers to the ratio between the inter-story shear strength of the i^{th} story ($V_{y,i}$) and the first story ($V_{y,1}$).

$$\Gamma_i = \frac{V_{y,i}}{V_{y,1}} \quad (20)$$

Additionally, the coefficient for the severity of degradation (τ) is required to determine the hysteric behavior. As shown in Eq. (21), it is defined as the ratio between areas of the pinching envelope (A_p) and full bilinear envelope (A_b) and its values are given in Table 5.18 of HAZUS [8], [71].

$$\tau = \frac{A_p}{A_b} \quad (21)$$

The flexural-shear coupling elastic continuum model was proposed by [23] to simulate the seismic responses and dynamic characteristics of tall buildings. The deformation modes of these structural systems are typically a combination of flexural deformation and shear deformation. Partial differential equations were used to describe the dynamic response of this model under a ground motion acceleration as follows:

$$\begin{aligned} \frac{\rho(x)}{EI_0} \frac{\partial^2 u(x,t)}{\partial t^2} + \frac{c(x)}{EI_0} \frac{\partial u(x,t)}{\partial t} + \frac{1}{H^4} \frac{\partial^2}{\partial x^2} \left(s(x) \frac{\partial^2 u(x,t)}{\partial x^2} \right) \\ - \frac{\alpha_0^2}{H^4} \frac{\partial}{\partial x} \left(s(x) \frac{\partial u(x,t)}{\partial x} \right) = - \frac{\rho(x)}{EI_0} \frac{\partial^2 u_g(x,t)}{\partial t^2} \end{aligned} \quad (22)$$

$$\alpha_0 = H (GA_0/EI_0)^{1/2} \quad (23)$$

$$EI(x) = EI_0 s(x), \quad GA(x) = GA_0 s(x) \quad (24)$$

where: $\rho(x)$ is the mass per unit length in the model; $c(x)$ is damping per length coefficient; x is a non-dimensional height (varies from 0 at the base to 1 at the top level); t is time; $u(x,t)$ is lateral displacement respecting discrete values of x and t . EI_0 and GA_0 refer to the flexural and shear stiffnesses at the model's base. H is the total height of the building. $EI(x)$ and $GA(x)$ are the flexural stiffness of the flexural beam and the shear stiffness of the shear beam along with the structural height, respectively. $s(x)$ is the dimensionless function that defines the stiffness variation along with the model's height, assuming that the variations of the flexural and shear stiffnesses

along the height are identical. Where, α_0 is a dimensionless parameter controlling the proportions of the flexural and shear deformations in the model. Assuming, $u_g(x, t)$ is the acceleration history of the ground motion. Furthermore, they investigated the relationship between α_0 values and different types of structures. **Table 11** identifies these recommended values, where the shear deformation dominates the deformation mode if α_0 is greater than 30.

Table 11: Approximate ranges of α_0 for different types of structures [23].

Type of structures	α_0
Shear wall structure	0-1.5
Combined moment-resisting frame and shear wall structure	1.5-5.0
Combined moment-resisting frame and braced frame structure	1.5-5.0
Frame structure	5.0-20

The nonlinear MDOF flexural-shear (NMFS) model was proposed by [16] to include nonlinear where the calibration process is summarized in **Figure 15** and it is divided into four steps:

(1) Calibration of the elastic parameters:

In this stage, the initial flexural and shear stiffness (EI, GA) values are estimated based on the modal analysis parameter: the period T_i , eigenvalue parameter γ_i , and the omega parameter ω_i for each I mode; as shown in Eqs. (25) and (26).

$$\omega_1^2 = \frac{EI}{\rho H^4} \gamma_1^2 (\gamma_1^2 + \alpha_0^2) \quad (25)$$

$$\alpha_0 = H \sqrt{\frac{GA}{EI}} \quad (26)$$

where α_0 is the flexural-shear stiffness ratio and can be calculated as follows

$$\frac{T_i}{T_1} = \frac{\gamma_1}{\gamma_i} \sqrt{\frac{\gamma_1^2 + \alpha_0^2}{\gamma_i^2 + \alpha_0^2}} \quad (27)$$

(2) Calibration of the yield point:

For the j^{th} story and n^{th} mode shapes, the total displacement/inter-story displacement ($u_{j,n}/\Delta u_{j,n}$) and the total rotation/inter-story rotation ($\theta_{j,n}/\Delta\theta_{j,n}$) are derived from the modal shapes ($\phi_{j,n}$) and the spectrum displacement (D_n)

$$u_{j,n} = \Gamma_n \phi_{j,n} D_n \quad (28)$$

$$\Delta u_{j,n} = u_{j,n} - u_{j-1,n} \quad (29)$$

$$\theta_{j,n} = \partial u_{j,n} / \partial z \quad (30)$$

$$\Delta\theta_{j,n} = \theta_{j,n} - \theta_{j-1,n} \quad (31)$$

The inter-story shear force ($V_{j,n}$) and the bending moment ($M_{j,n}$) for each mode shape are calculated based on Eqs. (32) and (33). Then they are combined using the square root of the sum of the squares (SRSS) to obtain the shear force ($V_{a,j}$) and bending moment ($M_{a,j}$) demands on each story (Eqs. (34) and (35)).

$$V_{j,n} = \Delta u_{j,n} GA/h_j \quad (32)$$

$$M_{j,n} = \Delta\theta_{j,n} EI/h_j \quad (33)$$

$$V_{a,j} = \sqrt{\sum V_{j,n}^2} \quad (34)$$

$$M_{a,j} = \sqrt{\sum M_{j,n}^2} \quad (35)$$

The values of ($V_{j,n}$) and ($M_{j,n}$) are adjusted to follow design specifications. The value of design inter-story shear force ($V_{d,j}$) is estimated according to Eq. (36), where (V_{base}) is the total shear force. The design inter-story moment ($M_{d,j}$) can be obtained according to (JGJ 3-2010) manual [72], where (h_w) is a critical height from Eq. (37).

$$V_{d,j} = \max[V_{a,j}, 0.2 V_{base}] \quad (36)$$

$$h_w = \max[2h_{story}, 0.1h_{wall}] \quad (37)$$

The yield overstrength parameter (Ω_y) is adopted to determine the yield strength for shear forces and bending moments as follows:

$$V_{y,j} = V_{d,j} \Omega_y \quad (38)$$

$$M_{y,j} = M_{d,j} \Omega_y \quad (39)$$

Finally, the calibrated yield displacement, ($\Delta u_{y,j}$) and rotation, ($\Delta\theta_{y,j}$) can be determined according to the equations below.

$$\Delta u_{y,j} = V_{y,j} \cdot h_j / GA \quad (40)$$

$$\Delta\theta_{y,j} = M_{y,j} \cdot h_j / EI \quad (41)$$

(3) Calibration of the peak point:

The plastic strength for each story shear spring ($V_{p,j}$) and flexural spring ($M_{p,j}$) can be derived directly by multiplying the corresponding yield value by the plastic overstrength factor (Ω_p).

$$V_{p,j} = V_{y,j} \Omega_p \quad (42)$$

$$M_{p,j} = M_{y,j} \Omega_p \quad (43)$$

For the bi-linear backbone curve, the peak displacement ($\Delta u_{p,j}$) and the peak rotation ($\Delta \theta_{p,j}$) are determined directly from plastic strengths and elastic stiffnesses as follows:

$$\Delta u_{p,j} = V_{p,j} \cdot h_j / GA \quad (44)$$

$$\Delta \theta_{p,j} = M_{p,j} \cdot h_j / EI \quad (45)$$

For the tri-linear backbone curve, peak values can be determined using two different methods:

- Stiffness reduction method:

The elastic stiffnesses for shear and bending are reduced by a reduction factor (η) according to ACI specifications [73].

$$G_r A = \eta GA \quad (46)$$

$$E_r I = \eta EI \quad (47)$$

Then, the peak displacement ($\Delta u_{p,j}$) and the peak rotation ($\Delta \theta_{p,j}$) are estimated using the reduced elastic stiffnesses (G_r, E_r).

$$\Delta u_{p,j} = V_{p,j} \cdot h_j / G_r A \quad (48)$$

$$\Delta \theta_{p,j} = M_{p,j} \cdot h_j / E_r I \quad (49)$$

- Ductility factor method:

In this method, the peak displacement and rotation on each story are determined based on the ductility factor (μ), determined as explained in Eq. (50).

$$\mu \Omega_p = D_p / D_y \quad (50)$$

$$\Delta u_{p,j} = \mu \Omega_p \Delta u_{y,j} \quad (51)$$

$$\Delta \theta_{p,j} = \mu \Omega_p \Delta \theta_{y,j} \quad (52)$$

(4) Calibration of the hysteretic parameter:

The degradation behavior through several hysteresees is adjusted using the (τ) coefficient defined using Eq. (21).

4.2 Pushover Analysis

Non-linear pushover analyses were performed using Opensees [6], to be the reference for calibrating refined FE models to simplified NMFS models. For each archetype model, three pushover analyses with different loading profiles (typically; linear, fundamental mode shape, and quadratic profiles) were conducted to define the most critical loading profile. **Table 12** shows the maximum estimated base shear within each profile which identifies that the quadratic is the most critical case (where: $F_{story} \propto \left(\frac{h_{story}}{H}\right)^2$).

Table 12: Estimated base shear for different pushover profiles.

Archetype	Maximum base shear for pushover profiles (KN)		
	Quadratic	Fundamental mode shape	Linear
M1_10F_50RC	4644.147	4961.205	5256.298
M2_15F_50RC	3089.289	3323.500	3493.262

4.3 Calibration Resulting Model

A trial heuristic algorithm was implemented to determine the best values for NMFS model parameters that achieve the closest pushover curve to the detailed FE models. The main optimization criteria were reducing the mean squared error between the two curves. The final values for: Ω_y , Ω_p and μ are reported in **Table 13**.

The final pushover curves compared to the FE model curves are plotted in Appendix B figures. The figures show how similar both models are in lateral behavior. Numerically, the relative errors for peak strength and total curve area are in 0.02, 0.08 worst cases, and less than 1.0E-05, and 0.04 average. While the MSE estimations were below 0.006 and in with an average value of 0.004. The efficiency of using NMFS is clarified by the difference in the time required for both models. As represented in **Table 21** the time required for the simplified models represents only 4/1000 of the

computational time required for the detailed models on average. Specifically, this is the ratio in arrange between 3/1000 to 6/1000.

Table 13: Estimated parameters for NMFS models

Archetype	NMFS models parameters				
	Ω_y	Ω_p	μ	EI (KN.m ⁴)	GA (KN.m ²)

Chapter 5: GIS Databases for Buildings, Ground Motions, and Risk Assessment Results

5.1 Input Ground Motions

As shown in **Table 1** and **Figure 27**, UAE is surrounded by regional and local seismic geological resources. The “Earthquake Scenario Simulation” component in R2D [9] was utilized to generate input ground motions. Multiple-point-earthquake sources were defined as listed in **Table 14**, which were collected from different resources to represent the surrounding seismic resources ([74]–[76]). An input ground motion was estimated at each neighbor's representative location (longitude and latitude) corresponding to every seismic source using Chiou & Youngs' prediction equation [77].

Table 14: Properties of earthquakes included in an earthquake simulation scenario.

Location	Date	Longitude	Latitude	M _w	Focal Depth (Km)
Chaldoran	24/11/1976	39.07	44.38	7.0	15
Tabas	16/09/1978	33.60	56.93	7.4	11

Masafi-Bani Hamid	13/09/2007	25.46	56.2	4.0	20

5.2 Buildings Database

This study included 17 archetypes that represent different occupancy classes, the number of stories, and design seismicity levels. Dubai has been segmented into 221 Neighbours by [65] and for each, the number of buildings was estimated approximately according to the population density. In addition, every area was classified according to its major occupancy into residential, commercial, industrial, and unidentified. In order to estimate the number of archetype buildings in a certain area, the archetypes have been grouped according to the occupancy class and a close number of stories, as defined

in **Table 15**. Then, hypothetical distribution ratios were defined to represent each group out of the total buildings in each neighborhood, as shown in **Table 16**.

Table 15: Definition and description of archetypes groups.

Archetypes Group	Description	Stories	Year Built	Archetypes
RES (1-5)	Low and Medium rise residential buildings	1-5	1981-2002	LR_RES_F1, LR_RES_F2, LR_RES_F3, LR_RES_F5
IND	Light industrial buildings	1	2003	LR_IND_F1
COM (3-7)	Low and Medium rise commercial buildings	3-7	1990 - 2010	LR_COM_F3, MR_COM_F6, MR_COM_F7
COM (10-20)	High-rise commercial buildings	10-20	2000	HR_COM_F10, HR_COM_F15, HR_COM_F20
COM (25-35)	High-rise commercial buildings	25-35	2005	HR_COM_F25, HR_COM_F30, HR_COM_F35
COM (40-50)	High-rise commercial buildings	40-50	2010	HR_COM_F40, HR_COM_F45, HR_COM_F50

Table 16: Hypothetically distribution ratios for archetypes in different neighbor classes.

Archetypes Group	Neighbour Class			
	Residential	Commercial	Industrial	unidentified
RES (1-5)	0.50	0.00	0.30	0.40
IND	0.00	0.00	0.70	0.10
COM (3-7)	0.25	0.25	0.15	0.15
COM (10-20)	0.15	0.25	0.00	0.15
COM (25-35)	0.05	0.25	0.00	0.10
COM (40-50)	0.05	0.25	0.00	0.10

5.3 Risk Assessment Results

The simulation process included three forms of inputs assigned two spatial attributes; ground motions, buildings database, and FE scripts for MCS, and NMFS models. While the results contain the expected collapse probability and losses for each building. The results were encapsulated in different scales: (1) overall studied city; (2)

neighbors; (3) neighbors classes; (4) archetypes group; and (5) archetypes. A detailed report is provided in the tables of Appendix C, while a summary representation is given as follows;

R2D [9] utilizes utilizes the PELICUN [78] package for the FEMA-P58 methodology to determine decision variables. FEMA developed a method to determine collapse probability by developing fragility curves. Fragility functions are calibrated using a variety a combination of analytical, experimental, and simulation methods. Analytical methods use mathematical equations to calculate the collapse probability of a building from the Engineering demanding parameters (EDPs) in addition to material properties, and asset classification. FEMA fragility functions are calibrated using a variety of methods, including:

- Expert judgment: FEMA uses the judgment of experts to develop fragility functions. Experts are typically engineers, architects, and seismologists who have experience in the design and construction of buildings.
- Data analysis: FEMA uses data from past earthquakes and other hazard events to develop fragility functions. This data includes information on the damage that was caused to buildings, the intensity of the hazard event, and the characteristics of the buildings.
- Simulation modeling: FEMA uses simulation models to develop fragility functions. Simulation models are computer programs that can be used to simulate the behavior of buildings under different loading conditions.

FEMA uses data from a variety of sources to calibrate its fragility functions, including:

- Earthquake damage surveys: FEMA conducts earthquake damage surveys to collect data on the damage that was caused to buildings in past earthquakes.
- Building codes: FEMA uses building codes to collect data on the design and construction of buildings.
- Engineering studies: FEMA uses engineering studies to collect data on the performance of buildings under different loading conditions.

FEMA uses the estimates of repair cost, repair time, and injuries to develop plans for responding to and recovering from disasters. These plans include disaster assistance and recovery planning. Disaster assistance provides financial assistance, grants, loans, and other forms of aid to individuals and businesses that have been affected by a

disaster. Recovery planning helps communities to identify the needs of the community and the steps that need to be taken to recover from a disaster. Here are some of the specific methods that FEMA uses to calculate repair cost, repair time, and injuries:

- Repair cost: FEMA calculates repair cost by considering the following factors: the type of damage that was caused to the building, the cost of materials and labor, the cost of demolition and removal, the cost of temporary housing
- Repair time: FEMA calculates repair time by considering the following factors: the type of damage that was caused to the building, the availability of materials and labor, The complexity of the repairs, the availability of funding
- Injuries: FEMA calculates injuries by considering the following factors: the type of damage that was caused to the building, the location of the building, the number of people in the building, and the severity of the damage.

Here are some examples of previous earthquake data used by FEMA to calibrate fragility functions:

1. San Francisco Earthquake, 1906: The San Francisco earthquake of 1906 was a magnitude 7.9 earthquake that caused widespread damage in San Francisco and the surrounding area. FEMA used data from this earthquake to develop fragility functions for buildings of different types and ages.
2. Northridge Earthquake, 1994: The Northridge earthquake of 1994 was a magnitude 6.7 earthquake that caused widespread damage in the Los Angeles area. FEMA used data from this earthquake to improve the accuracy of its fragility functions.
3. Kobe Earthquake, 1995: The Kobe earthquake of 1995 was a magnitude 7.2 earthquake that caused widespread damage in Kobe, Japan. FEMA used data from this earthquake to develop fragility functions for buildings in areas with high seismic risk.
4. Haiti Earthquake, 2010: The Haiti earthquake of 2010 was a magnitude 7.0 earthquake that caused widespread damage in Haiti. FEMA used data from this earthquake to improve the accuracy of its fragility functions for buildings in developing countries.

5.3.1 Collapse Probability:

The obtained results can be summarized as follows:

- The collapse probability for the modeled buildings can differ from 0.00 % to 60% with a mean value of almost 4%. The “LR_RES_F1” archetype represents the highest collapse probability ratio is slightly less than 8%, while the lowest ratio is 0.00 % expected for the “LR_IND_F1” archetype, shown in **Figure 31 (c)**.
- For concrete structures, the expected collapse ratios are in a range from 3% to 8%, from 1.2% to 3.5%, and from 0.2% to 2.3% for low-rise, medium-rise, and high-rise archetypes respectively.
- In other words, “RES (1-5)” is the highest archetypes group with an expected collapse probability of 5.5%. The collapse probability for commercial concrete structures decreases respecting the height from 3% for “COM (3-7)” to 0.2% for “COM (40-50)”, shown in **Figure 31 (b)**.
- As expected residential neighbors have the highest mean collapse probability of almost 4%, and commercial neighbors have the lowest ratio of 0.8%, while the ratios for industrial and unidentified neighbors are 1.8% and 3.1% as represented in **Figure 31 (a)**, respectively.
- Projecting these results on a GIS scale leads to the choropleth map shown in **Figure 36 (a)**, which determines the mean collapse probability for Dubai’s neighbors.

5.3.2 Repair Cost to Replacement Cost Ratio:

The monetary losses due to replacement or repair are a factual parameter in the assessment of earthquake disasters, which is depending on the collapse probability, construction material (Steel, Concrete,... etc.), and the structure system. These factors are reflected in the estimations as follows:

- The highest archetype for the repair-to-replacement ratio is the single-story masonry building “LR_RES_F1” with 28%, then the light steel industrial structure “LR_IND_F1” with 26%, as shown in **Figure 32 (c)**.
- The average ratio for residential archetypes is 21 % and for commercial archetypes groups in a range from for “COM (3-7)” group 12 % to 2% for the “COM (40-50)” group, as represented in **Figure 32 (b)**.

- For the GIS scale, the average losses for neighbors' classes can be ordered in descending as industrial (23%), residential (15%), unidentified (11.5%), and commercial (4.5%), see **Figure 32** (a).
- Additionally, the expected losses per individual neighbor were represented in **Figure 36** (b), which vary from 0% to 35%. Finally, the average cost for the cumulative city is expected to be 14% accompanied by a 0.25 standard deviation.

5.3.3 Repair Time:

Similar to the repair cost, the required time for repairs is related to construction materials, and the structural system. The key values are listed below:

- **Figure 33** (d) clarifies that the “LR_IND_F1” archetype requires the most number of days for repairs (223 days for mean value) with a significant difference from other archetypes.
- “LR_RES_F1” is the 2nd highest archetype in repair time with 29 days associated with a 49 standard deviation.
- The average repair days required for concrete archetypes are 25 for low-rise, 16 for medium-rise buildings, and in a range from 25 to 4 for high-rise buildings.
- As represented in **Figure 33** (c), the average required repair days for residential archetypes is 25 days, and for commercial archetypes groups in a range from 18 for the “COM (3-7)” group to 6 days for the “COM (40-50)” group.
- **Figure 33** (b) shows the repair time probabilities for different neighbors' classes. The mean values can be ordered in descending as industrial (148 days), unidentified (48 days), residential (20 days), and commercial (11 days).
- The overall estimated probability is 22 days associated with a 52 standard deviation, as referred to in **Figure 33** (a).
- Finally, **Figure 36** (c) includes the choropleth map for the expected repair time for the studied neighbors in the form of a colored scale from 0 to 220 days.

5.3.4 Injuries:

The expected injuries of the total occupancy population are classified in an ascending severity order from one to four. The estimated injuries are summarized as follows:

- The mean total injuries for the studied region are estimated to be approximately 1.5% of the population, 62% of them represent the lowest severity while 10% for the highest severity, See **Figure 34**.
- As a result of the collapse probabilities and expected damage variables, the expected average injuries are from 1.7% to 6.5% for low-rise archetypes, from 0.2% to 5.3%, for medium-rise archetypes, and from 0.04% to zero for high-rise archetypes, as shown **Figure 35**.
- The “LR_RES_F1” archetype has the highest total injuries with 6.5% distributed as 83%, 16.5 % for 1st and 2nd severity, and 0.02% for 3rd and 4th. Then, the “LR_IND_F1” archetype with 5%. and the ratios of the injuries' severity are 60%, 24%, 5%, and 10% from lowest to highest. While for concrete models the total injuries are 2 % in the worst case 61% for the lowest severity and 10% for the highest.
- The mean values for neighbors classes can be ordered in descending as industrial (4.1%), residential (1.6%), unidentified (1.1%), and commercial (0.1%), see Figure 34 (c).
- Finally, the representative map for injuries distributed per studied neighbors can be found in **Figure 34 (b)**.

Chapter 6: Conclusions and Recommendations.

6.1 Summary

The location of UAE is surrounded by multiple earthquake sources both regionally (like; the Zagros Fold and Thrust Belt, and the Makran Subduction Zone), and locally (like; Oman Mountains, and the Dibba Line), as obtained in **Table 1**, **Figure 1**, and **Figure 27**. Based on observations and several studies from 2000-2006, three seismic events per year are expected in this region. The UAE construction sector expenditure occurred in an era when this region suffered from a lack of data related to seismic events and design response parameters. The diversity among studies was from no seismic hazard to very high seismicity, as shown in **Table 5**, so a regional earthquakes simulation is required to estimate the expected losses. This simulation process requires constructing databases for all buildings with their structural and spatial attributes as existed in reality. It is a challenging process that requires excessive data collection work, in addition to computational demands, and results uncertainties. For reducing the computational effort required for structure analysis, many methodologies were developed to calibrate refined FE models to simplified models that can present a similar lateral resistance behavior with few DOFs. On the other hand, the PEER PBEE methodology was established to estimate losses in a probabilistic manner that incorporates UQ with all loss estimation analyses. This study provided a prototype regional earthquake simulation for Dubai, with few assumptions to fill the unavailable data. The study depended on 17 archetypes that vary in occupancy, building height, structure type, and design seismic intensity, as shown in **Table 2**, and **Table 3**. The collected data for neighbors (like; locations, occupancy class, and the total number of buildings) were implemented to define the GIS databases, while distributing archetypes to GIS locations following arbitrary assumptions. For structure responses, the MCS model, proposed by [19], was implemented for low-rise, and medium-rise models, while the NMFS models were used for high-rise models. Calibrating NMFS models followed the process identified by [23], and showed the simplified models demand only 0.003 to 0.0006 of the time required time for refined FE models. The earthquake scenario component at R2D [9] was utilized to generate input ground motions per neighbor location, where the input earthquake source points were collected from different studies and summarized in **Table 14**. The simulation outputs included the collapse probability, repair cost, repair time, and expected injuries for every building in

the assumed database. Finally, the results had been filtered and grouped in scales of neighbors, neighbor classes, archetypes, and archetypes groups to analyze the impact of different input parameters.

6.2 Conclusion

The conclusion of configured outputs for studied archetypes is as follows:

- The “LR_RES_F1” and “LR_IND_F1” archetypes have different results patterns than other archetypes. “LR_RES_F1” is a bearing masonry wall residential house for a single family that was built more than 40 years ago. “LR_IND_F1” is a steel moment-framing structure for a light industrial purpose constructed almost 20 years ago, while other archetypes represent concrete structures for residential or commercial assets. “LR_RES_F1” produces the highest collapse probability of 8%, repair cost of 28%, and total injuries of 6.5%. Despite the “LR_IND_F1” being the lowest archetype in collapse probability (equals zero), it produces 2nd highest repair cost and total injury losses (26%, and 5% respectively). Moreover, it represents the longest repair time by 223 days with a significant difference from other models (2nd longest repair time equals 29 days).
- The seismic design spectrum is the key factor in scaling all loss parameters. The archetypes were designed assuming low seismic intensity had a collapse probability range from 4.6% to 8%, repair cost from 20% to 28.5%, and total injuries from 1.7% to 6.6%. For medium-rise archetypes, these results decrease: from 1.3% to 3.4% for collapse probability, and from 9.5% to 12.6% for the repair cost. and from 0.2% to 5.3%, for injuries. While archetypes designed for a high seismic intensity achieved the lowest loss values: from 0.2% to 2.3%, from 1.4% to 7%, and from 0.04% to zero for collapse probability, repair cost, and injuries, respectively.

The obtained results for neighbors' occupancy according to the estimated number of assets and assumed archetypes distributions weights are:

- The residential neighbors possess the highest collapse probability estimation. They have an expected collapse probability of 4%, a repair cost-to-replacement cost ratio of 15%, an average expected 20 days for repairs, and total injuries of 1.6% (1%, 0.4%, 0.08%, and 0.2% for different severity levels, ascendingly).

- The average expected collapse probability in a commercial is 0.8%. Their estimated repair costs and time are 4.6% and 11 days. The expected total injuries are only 0.1%, 65% of them for the lowest severity and only 9% represent the hardest cases.
- The industrial areas possess the highest values for loss variables except for the collapse probability which is 2%. Their estimated repair costs and time are 23% and 148 days. The expected total injuries are 4%, 79% of them for the lowest severity and only 2% represent the hardest cases.
- For neighbors with undefined classifications, the estimated loss variables are; a collapse probability of 3%, a repair cost-to-replacement cost ratio of 11.6%, an average expected 48 days for repairs, and total injuries of 1.1% (0.9%, 0.2%, 0.00%, and 0.01% for different severity levels, ascendingly).

Finally, the overall expected losses as average values are; a collapse probability of 3.6%, a repair cost is 14% of the total replacement cost, a repair time of 22 days for each asset, and total injuries of almost 1.5% of the total population. The injuries differ from lowest to highest severity as; 1%, 0.4%, 0.07%, and 0.15% respectively.

6.3 Recommendations

According to the estimated results, two major recommendations outcome from this study. The first recommendation is to design buildings in Dubai's region considering a conservative seismic hazard estimate (high or moderate), which will contribute to decreasing all loss variables. This recommendation was already introduced by a previous seismic hazard study [15]. Additionally, it is recommended to give a higher priority to evaluating structures that are designed assuming low seismic intensity as the built status, to be renovated or replaced. A higher priority should be given to assets with more populations and older construction time.

In 2004, J.P. Moehle and M.E. Jackson published a book [79] that provides a comprehensive overview of the principles and practices of earthquake retrofitting of existing buildings. The book begins by discussing the importance of earthquake retrofitting and the different types of retrofitting techniques. It then goes on to discuss the specific retrofitting methods that are used for different types of buildings, such as concrete buildings, steel buildings, and wood buildings. This book provides a comprehensive overview of the principles and practices of earthquake retrofitting of

existing buildings. The book begins by discussing the importance of earthquake retrofitting and the different types of retrofitting techniques. It then goes on to discuss the specific retrofitting methods that are used for different types of buildings, such as concrete buildings, steel buildings, and wood buildings. Here are some of the specific methods that can be used to check the earthquake resistance of already-built assets:

- Visual inspection: This involves inspecting the asset for any signs of damage or deterioration that could compromise its earthquake resistance.
- Non-destructive testing: This involves using non-destructive testing methods, such as ultrasonic testing or ground-penetrating radar, to assess the condition of the asset's structural elements.
- Destructive testing: This involves removing samples of the asset's structural elements to assess their strength and ductility.

The specific methods that are used will depend on the type of asset and the level of detail required. However, all of the methods mentioned above can be used to provide valuable information about the earthquake resistance of an asset.

6.4 Future Work and Possible Extensions

The proposed study achieved some enhancements to the previous Dubai regional seismic evaluation [65], like; considering more archetypes models, implementing earthquake scenario simulation, and adopting the HAZUS dataset [8] in estimating losses. But it still represents only a prototypal example that is limited to a few assumed models, and all high-rise archetypes follow the same plan layout and the LFRS. For extensions, adding more archetypes that contain different structural systems and a variation in material properties could be an accountable expenditure for the research significance. The long-term is to produce a regional simulation that reflects reality. This kind of accuracy required a long effort in data collection and the development of multiple programs to generate required building attributes and non-linear models from commercial documents/formats like 2D drawings or 3D models.

The research was based on FEMA-P58 methodology to determine decision variables. These methods depend on an analytical procedure for data North-America earthquakes where the community response, Cultural behavior with such disasters, and governmental and decision-making or preparedness, and financial conditions are

different from the UAE community. So Working on calibration Fragility curves for UAE simulation is a key path to improve the accuracy and reality of similar research. Over the past few years, the advancement of seismic risk assessment systems have been significant. However, this progress has created a need for further development in incremental dynamic analyses. Despite this, these systems have the potential to make significant contributions to various areas of structural engineering applications, such as structural assessment [80]–[85] and the application of soft computing techniques in civil engineering [86]–[95]. Additionally, they can aid in the evaluation of structures under various lateral loads (e.g., seismic [96]–[128] and wind [129]–[133] loads), as well as many other applications [134]–[199].

Vita

Ahmed Mansour Maky was born in 1993, in Aswan, Egypt and he also received his primary and secondary education there. He received his B.Sc. degree in Civil Engineering Engineering from Aswan University in 201. From 2019 to 2020, he worked as a Research and Development Engineer in Elibre DMCC, Cairo.

In September 2020, he joined the Civil Engineering master's program in the American University of Sharjah as a graduate research and teaching assistant. During his master's study, he co-authored 3 papers that were presented in international conferences and journals. His research interests are in (e.g. Finite Elements Analysis, Computational Science and Earthquake Engineering).
